3. RM versus PR
4. General Recursive Functions
5. Church-Turing Thesis
Machine models of computation are easy to describe and very natural. However, constructing any specific machine for a particular computation is rather tedious.

Almost always it is much preferable to use a programming language to explain how a computation should be performed.

There are lots of standard programming languages that all could be used to give alternative definitions of computability: Algol, Pascal, C, C++, Java, perl, ...  
The problem with all of these is that it is quite difficult to give a careful explanation of the semantics of the programs written in any of these languages.
To avoid problems with semantics we will introduce a language that has only one data type: $\mathbb{N}$, the non-negative integers.

We will define the so-called primitive recursive functions, maps of the form

$$f : \mathbb{N}^n \rightarrow \mathbb{N}$$

that can be computed intuitively using no more than a limited type of recursion.

We use induction to define this class of functions: we select a few simple basic functions and build up more complicated ones by composition and a limited type of recursion.
There are three types of basic functions.

- **Constants zero** \( C^n : \mathbb{N}^n \to \mathbb{N}, C^n(x_1, \ldots, x_n) = 0 \)
- **Projections** \( P^n_i : \mathbb{N}^n \to \mathbb{N}, P^n_i(x_1, \ldots, x_n) = x_i \)
- **Successor function** \( S : \mathbb{N} \to \mathbb{N}, S(x) = x + 1 \)

This is a rather spartan set of built-in functions, but as we will see it’s all we need.

Needless to say, these functions are trivially computable.
Composition

Given functions $g_i : \mathbb{N}^m \rightarrow \mathbb{N}$ for $i = 1, \ldots, n$, $h : \mathbb{N}^n \rightarrow \mathbb{N}$, we define a new function $f : \mathbb{N}^m \rightarrow \mathbb{N}$ by composition as follows:

$$f(x) = h(g_1(x), \ldots, g_n(x))$$

Notation: we write $\text{Comp}[h, g_1, \ldots, g_n]$ or simply $h \circ (g_1, \ldots, g_n)$ inspired by the well-known special case $m = 1$:

$$(h \circ g)(x) = h(g(x)).$$
• **Primitive recursion**

Given \( h : \mathbb{N}^{n+2} \to \mathbb{N} \) and \( g : \mathbb{N}^n \to \mathbb{N} \), we define a new function \( f : \mathbb{N}^{n+1} \to \mathbb{N} \) by

\[
\begin{align*}
  f(0, y) &= g(y) \\
  f(x + 1, y) &= h(x, f(x, y), y)
\end{align*}
\]

Write Prec\([h, g]\) for this function.

**Definition**

A function is **primitive recursive (p.r.)** if it can be constructed from the basic functions by applying composition and primitive recursion.
Example: Factorials

The standard definition of the factorial function uses recursion like so:

\[
\begin{align*}
f(0) &= 1 \\
f(x + 1) &= (x + 1) \cdot f(x)
\end{align*}
\]

To write the factorial function in the form \( f = \text{Prec}[h, g] \) we need

\[
\begin{align*}
g : \mathbb{N}^0 &\rightarrow \mathbb{N}, \quad g() = 1 \\
h : \mathbb{N}^2 &\rightarrow \mathbb{N}, \quad h(u, v) = (u + 1) \cdot v
\end{align*}
\]

\( g \) is none other than \( S \circ C^0 \) and \( h \) is multiplication combined with the successor function:

\[
f = \text{Prec}[\text{mult} \circ (S \circ P_1^2, P_2^2), S \circ C^0]
\]
To get multiplication we use another recursion:

\[
\text{mult}(0, y) = 0 \\
\text{mult}(x + 1, y) = \text{add}(\text{mult}(x, y), y)
\]

Here we use addition, which can in turn be defined by yet another recursion:

\[
\text{add}(0, y) = y \\
\text{add}(x + 1, y) = S(\text{add}(x, y))
\]

Since \(S\) is a basic function we have a proof that multiplication is primitive recursive.
These equational definitions of basic arithmetic functions dates back to Dedekind’s 1888 paper “Was sind und was sollen die Zahlen?”
It is a good idea to go through the definitions of all the standard basic arithmetic functions from the p.r. point of view.

\[
\begin{align*}
\text{add} & = \text{Prec}[S \circ P^3_2, P^1_1] \\
\text{mult} & = \text{Prec}[\text{add} \circ (P^3_2, P^3_3), C^1] \\
\text{pred} & = \text{Prec}[P^2_1, C^0] \\
\text{sub}' & = \text{Prec}[\text{pred} \circ P^3_2, P^1_1] \\
\text{sub} & = \text{sub}' \circ (P^2_2, P^2_1)
\end{align*}
\]

Since we are dealing with \( \mathbb{N} \) rather than \( \mathbb{Z} \), sub here is proper subtraction: \( x \cdot y = x - y \) whenever \( x \geq y \), and 0 otherwise.

**Exercise**

*Show that all these functions behave as expected.*
■ Primitive Recursive Functions

2 Pushing Primitive Recursion

■ RM versus PR

■ General Recursive Functions

■ Church-Turing Thesis
Apparently we lack a mechanism for definition-by-cases:

\[ f(x) = \begin{cases} 
3 & \text{if } x < 5, \\
x^2 & \text{otherwise.} 
\end{cases} \]

We know that \( x \mapsto 3 \) and \( x \mapsto x^2 \) are p.r., but is \( f \) also p.r.?

And how about more complicated operations such as the GCD or the function that enumerates prime numbers?
Definition

Let $g, h : \mathbb{N}^n \to \mathbb{N}$ and $R \subseteq \mathbb{N}^n$.

Define $f = \text{DC}[g, h, R]$ by

$$f(x) = \begin{cases} g(x) & \text{if } x \in R, \\ h(x) & \text{otherwise.} \end{cases}$$

We want to show that definition by cases is admissible in the sense that when applied to primitive recursive functions/relations we obtain another primitive recursive function.

Note that we need express the relation $R$ as a function; more on that in a minute.
The first step towards implementing definition-by-cases is a bit strange, but we will see that the next function is actually quite useful.

The \textit{sign} function is defined by

$$\text{sign}(x) = \min(1, x)$$

so that \(\text{sign}(0) = 0\) and \(\text{sign}(x) = 1\) for all \(x \geq 1\). Sign is primitive recursive: \(\text{Prec}[S \circ C^2, C^0]\)

Similarly the \textit{inverted sign} function is primitive recursive:

$$\overline{\text{sign}}(x) = 1 - \text{sign}(x)$$
Define $E : \mathbb{N}^2 \rightarrow \mathbb{N}$ by

$$E = \text{sign} \circ \text{add} \circ (\text{sub} \circ (P_2^1, P_2^2), \text{sub} \circ (P_2^2, P_1^2))$$

Or sloppy but more intelligible:

$$E(x, y) = \text{sign}((x \cdot y) + (y \cdot x))$$

Then $E(x, y) = 1$ iff $x = y$, and 0 otherwise. Hence we can express equality as a primitive recursive function.

Even better, we can get other order relations such as $\leq$, $<$, $\geq$ . . .

So, the fact that our language lacks relations is not really a problem; we can express them as functions.
As before we can use the characteristic function of a relation $R$

$$\text{char}_R(x) = \begin{cases} 
1 & x \in R \\
0 & \text{otherwise.}
\end{cases}$$

to translate relations into functions.

**Definition**

A relation is **primitive recursive** if its characteristic function is primitive recursive.

The same method works for any notion of computable function: given a class of functions (RM-computable, p.r., polynomial time, whatever).
Proposition

The primitive recursive relations are closed under intersection, union and complement.

Proof.

\[
\begin{align*}
\text{char}_{R \cap S} &= \text{mult} \circ (\text{char}_R, \text{char}_S) \\
\text{char}_{R \cup S} &= \text{sign} \circ \text{add} \circ (\text{char}_R, \text{char}_S) \\
\text{char}_{N - R} &= \text{sub} \circ (S \circ C^m, \text{char}_R)
\end{align*}
\]

The proof is slightly different from the argument for decidable relations but it's really the same idea.

Exercise

Show that every finite set is primitive recursive.
Note what is really going on here: we are using arithmetic to express logical concepts such as disjunction.

The fact that this translation is possible, and requires very little on the side of arithmetic, is a central reason for the algorithmic difficulty of many arithmetic problems: logic is hard, by implication arithmetic is also difficult.

For example, finding solutions of Diophantine equations is hard.

Incidentally, primitive recursive functions were used extensively by K. Gödel in his incompleteness proof.
DC is Admissible

Proposition

If \( g, h, R \) are primitive recursive, then \( f = \text{DC}[g, h, R] \) is also primitive recursive.

Proof.

\[
f = \text{add} \circ (\text{mult} \circ (\text{char}_R, g), \text{mult} \circ (\overline{\text{char}_R}, h))
\]

Less cryptically

\[
f(x) = \text{char}_R(x) \cdot g(x) + \overline{\text{char}_R}(x) \cdot h(x)
\]

Since either \( \text{char}_R(x) = 0 \) and \( \overline{\text{char}_R}(x) = 1 \), or the other way around, we get the desired behavior. \( \square \)
Proposition

Let \( g : \mathbb{N}^{n+1} \to \mathbb{N} \) be primitive recursive, and define

\[
 f(x, y) = \sum_{z < x} g(z, y)
\]

Then \( f : \mathbb{N}^{n+1} \to \mathbb{N} \) is again primitive recursive. The same holds for products.

Proof.

\[
\text{Prec[add} \circ (g \circ (P_{2^{n+3}}, \ldots, P_{n+2}), P_{2^{n+2}}), C^n]}
\]

Exercise

Show that \( f(x, y) = \sum_{z < h(x)} g(z, y) \) is primitive recursive when \( h \) is primitive recursive and strictly monotonic.
A particularly important algorithmic technique is search over some finite domain. For example, in factoring \( n \) we are searching over an interval \([2, n - 1]\) for a number that divides \( n \).

We can model search in the realm of p.r. functions as follows.

**Definition (Bounded Search)**

Let \( g : \mathbb{N}^{n+1} \to \mathbb{N} \). Then \( f = BS[g] : \mathbb{N}^{n+1} \to \mathbb{N} \) is the function defined by

\[
f(x, y) = \begin{cases} 
\min \{ z < x \mid g(z, y) = 0 \} & \text{if } z \text{ exists,} \\
x & \text{otherwise}.
\end{cases}
\]
One can show that bounded search adds nothing to the class of p.r. functions.

**Proposition**

*If* $g$ *is primitive recursive then so is* $\text{BS}[g]$.

This would usually be expressed as “primitive recursive functions are closed under bounded search.”
This can be pushed a little further: the search does not have to end at $x$ but it can extend to a primitive recursive function of $x$ and $y$.

$$f(x, y) = \begin{cases} \min(z < h(x, y) \mid g(z, y) = 0) & \text{if } z \text{ exists}, \\ h(x, y) & \text{otherwise}. \end{cases}$$

Dire Warning:

But we have to have a p.r. bound, unbounded search as in

$$\min(z \mid g(z, y) = 0)$$

is not an admissible operation; not even when there is a suitable $z$ for each $y$. 
Claim

The divisibility relation \( \text{div}(x, y) \) is primitive recursive.

Note that

\[
\text{div}(x, y) \iff \exists z, 1 \leq z \leq y \ (x \cdot z = y)
\]

so that bounded search intuitively should suffice to obtain divisibility. Formally, we have already seen that the characteristic function \( M(z, x, y) \) of \( x \cdot z = y \) is p.r. But then

\[
\text{sign} \left( \sum_{z \leq y} M(z, x, y) \right)
\]

is the p.r. characteristic function of \( \text{div} \).
Claim

The primality relation is primitive recursive.

Intuitively, this is true since $x$ is prime iff

$$1 < x \text{ and } \forall z < x \ (\text{div}(z, x) \Rightarrow z = 1).$$

Claim

The next prime function $f(x) = \min \{ z > x \mid z \text{ prime} \}$ is p.r.

This follows from the fact that bounded search again suffices:

$$f(x) \leq 2x \quad \text{for } x \geq 1.$$ 

This bounding argument requires number theory (a white lie).
Claim

The function $n \mapsto p_n$ where $p_n$ is the $n$th prime is primitive recursive.

To see this we can iterate the “next prime” function from the last claim:

\[
p(0) = 2 \\
p(n + 1) = f(p(n))
\]
Arguments like the ones for basic number theory suggest another type of closure properties, with a more logical flavor.

**Definition (Bounded quantifiers)**

\[ P_{\forall}(x, y) \iff \forall z < x \ P(z, y) \quad \text{and} \quad P_{\exists}(x, y) \iff \exists z < x \ P(z, y). \]

Note that \( P_{\forall}(0, y) = \text{true} \) and \( P_{\exists}(0, y) = \text{false} \).

Informally,

\[ P_{\forall}(x, y) \iff P(0, y) \land P(1, y) \land \ldots \land P(x - 1, y) \]

and likewise for \( P_{\exists} \).
Bounded quantification is really just a special case of bounded search: for $P_\exists(x, y)$ we search for a witness $z < x$ such that $P(z, y)$ holds. Generalizes to $\exists z < h(x, y) P(z, y)$ and $\forall z < h(x, y) P(z, y)$.

**Proposition**

*Primitive recursive relations are closed under bounded quantification.*

**Proof.**

\[
\text{char}_{P_\forall}(x, y) = \prod_{z < x} \text{char}_{P}(z, y)
\]

\[
\text{char}_{P_\exists}(x, y) = \text{sign}\left(\sum_{z < x} \text{char}_{P}(z, y)\right)
\]
Exercises

Exercise

Give a proof that primitive recursive functions are closed under definition by multiple cases.

Exercise

Show in detail that the function $n \mapsto p_n$ where $p_n$ is the $n$th prime is primitive recursive. How large is the p.r. expression defining the function?
- Primitive Recursive Functions
- Pushing Primitive Recursion
- RM versus PR
- General Recursive Functions
- Church-Turing Thesis
Burning Question: How does the computational strength of register machines compare to primitive recursive functions?

It is a labor of love to check that any p.r. function can indeed be computed by a RM.

This comes down to building a RM compiler/interpreter for p.r. functions. Since we can use structural induction this is not hard in principle; we can use a similar approach as in the construction of the universal RM.
The cheap answer is to point out that some RM-computable functions are not total, so they cannot be p.r.

True, but utterly boring. Here are the right questions:

- How much of a RM computation is primitive recursive?
- Is there a total RM-computable function that is not primitive recursive?
In a Nutshell

Using the coding machinery from last time it is not hard to see that the relation “RM $M$ moves from configuration $C$ to configuration $C'$ in $t$ steps” is primitive recursive. But when we try to deal with “RM $M$ moves from $C$ to $C'$ in some number of steps” things fall apart: there is no obvious way to find a primitive recursive bound on the number of steps.

It is perfectly reasonable to conjecture that RM-computable is strictly stronger than primitive recursive, but coming up with a nice example is rather difficult.
Proposition

Let $M$ be a register machine. The $t$-step relation

$$C |^t_M C'$$

is primitive recursive, uniformly in $t$ and $M$.

Of course, this assumes a proper coding method for configurations and register machines.

Since configurations are of the form

$$(p, (x_1, \ldots, x_n))$$

where $p$ and $x_i$ are natural numbers this is a straightforward application of sequence numbers.
Likewise we can encode a whole sequence of configurations

\[ C = C_0, C_1, \ldots, C_{t-1}, C_t = C' \]

again by a single integer.

And we can check in a p.r. way that \( C' \mid M_t C' \).

A crucial ingredient here is that the size of the \( C_i \) is bounded by something like the size of \( C \) plus \( t \), so we can bound the size of the sequence number coding the whole computation given just the size of \( C \) and \( t \).

**Exercise**

*Figure out exactly what is meant by the last comment.*
Now suppose we want to push this argument further to deal with whole computations. We would like the transitive closure

\[ C' \xrightarrow{M} C' \]

to be primitive recursive.

If we could bound the number of steps in the computation by some p.r. function of \( C \) then we could perform a brute-force search.

However, there is no reason why such a bound should exist, the number of steps needed to get from \( C' \) to \( C'' \) could be enormous.

Again, there is a huge difference between bounded and unbounded search.
So, can we concoct a register computable function that is total but fails to be primitive recursive?

One way to tackle this problem is to make sure the function grows faster than any primitive recursive one, again by exploiting the inductive structure of the these functions.
The Ackermann function $A : \mathbb{N} \times \mathbb{N} \to \mathbb{N}$ is defined by

$$A(0, y) = y^+$$
$$A(x^+, 0) = A(x, 1)$$
$$A(x^+, y^+) = A(x, A(x^+, y))$$

where $x^+$ is shorthand for $x + 1$.

Note the odious double recursion – on the surface, this looks more complicated than primitive recursion.
Here is a bit of C code that implements the Ackermann function (assuming that we have infinite precision integers).

```c
int acker(int x, int y)
{
    return( x ? (acker( x-1, y ? acker( x, y-1 ): 1 )): y+1 );
}
```

All the work of organizing the nested recursion is handled by the compiler and the execution stack. Of course, doing this on a register machine is a bit more challenging, but it can be done.
It is useful to think of Ackermann’s function as a family of unary functions \((A_x)_{x \geq 0}\) where \(A_x(y) = A(x, y)\).

The critical part of the definition then looks like so:

\[
A_x + (y) = \begin{cases} 
A_x(1) & \text{if } y = 0, \\
A_x(A_x + (y - 1)) & \text{otherwise.}
\end{cases}
\]

From this it follows easily by induction that

**Claim**

*Each function \(A_x\) is primitive recursive.*
The first 4 levels of the Ackermann hierarchy are easy to understand, though $A_4$ starts causing problems, the stack of 2’s has height about $2^y$. 

\[
\begin{align*}
A(0, y) &= y^+ \\
A(1, y) &= y^{++} \\
A(2, y) &= 2y + 3 \\
A(3, y) &= 2^{y+3} - 3 \\
A(4, y) &\approx 2^{2^{\cdots^2}}
\end{align*}
\]
The Mystery of $A(6, 6)$

But if we continue just a few more levels darkness befalls.

\[ A(5, y) \approx \text{super-super exponentiation} \]
\[ A(6, y) \approx \text{an unspeakable horror} \]
\[ A(7, y) \approx \text{speechless} \]

For level 5, one can get some vague understanding of iterated super-exponentiation, but things start to get murky.

At level 6 we recurse over the already nebulous level 5 function, and things really start to fall apart.

At level 6 Wittgenstein comes to mind: “Wovon man nicht sprechen kann, darüber muss man schweigen.”
Theorem

The Ackermann function dominates every primitive recursive function in the sense that there is a $k$ such that

$$f(x) < A(k, \max x).$$

Hence $A$ is not primitive recursive.

Sketch of proof.

One can argue by induction on the buildup of $f$.

The atomic functions are easy to deal with.

The interesting part is to show that the property is preserved during an application of composition and of primitive recursion. Alas, the details are rather tedious.
One might think that the only purpose of the Ackermann function is to refute the claim that computable is the same as p.r. Surprisingly, the function pops up in the analysis of the Union/Find algorithm (with ranking and path compression).

The running time of Union/Find differs from linear only by a minuscule amount, which is something like the inverse of the Ackermann function. But in general anything beyond level 3.5 of the Ackermann hierarchy is irrelevant for practical computation.

**Exercise**

*Read an algorithms text that analyzes the run time of the Union/Find method.*
The recursive definition from above is close to Ackermann’s original approach. Here is an alternative based on iteration.

\[ B_1(x) = 2x \]
\[ B_{k+1}(x) = B_k^x(1) \]

So \( B_1 \) is doubling, \( B_2 \) exponentiation, \( B_3 \) super-exponentiation and so on.

In general, \( B_k \) is closely related to \( A_{k+1} \).
Recall the subsequence ordering on words where $u = u_1 \ldots u_n$ precedes $v = v_1 v_2 \ldots v_m$ if there exists a strictly increasing sequence $1 \leq i_1 < i_2 < \ldots < i_n \leq m$ of indices such that $u = v_{i_1} v_{i_2} \ldots v_{i_n}$.

We write $u \sqsubseteq v$.

Subsequence order is not total unless the alphabet has size 1.

Note that subsequence order is independent of any underlying order of the alphabet (unlike, say, lexicographic or length-lex order).
Theorem

Every anti-chain in the subsequence order is finite.

Proof. Here is the Nash-Williams proof: assume there is an anti-chain. For each $n$, let $x_n$ be the length-lex minimal word such that $x_0, x_1, \ldots, x_n$ starts an anti-chain, producing a sequence $x = (x_i)$.

For any sequence of words $y = (y_i)$ and a letter $a$ define $a^{-1}y$ to be the sequence consisting of all words in $y$ starting with letter $a$, and with $a$ removed.

Since the alphabet is finite, there exists a letter $a$ such that $x' = a^{-1}x$ is an anti-chain. But then $x'_0 < x_0$, contradiction.

$\square$
For a finite or infinite word $x$ write $x[i]$ for the block $x_i, x_{i+1}, \ldots, x_{2i}$. We will always assume that $i \leq |x|/2$ when $x$ is finite.

A word is self-avoiding if for $i < j$ the block $x[i]$ is not a subsequence of $x[j]$.

The following is a consequence of Higman’s theorem.

**Theorem**

*Every self-avoiding word is finite.*

By the last theorem we can define

$$\alpha(k) = \text{length of longest self-avoiding word over } \Sigma_k$$
Trivially, $\alpha(1) = 3$.

A little work shows that $\alpha(2) = 11$, as witnessed by $01110000000$.

But

$$\alpha(3) > B_{7198}(158386),$$

an incomprehensibly large number.

It is truly surprising that a function with as simple a definition as $\alpha$ should exhibit this kind of growth.
- Primitive Recursive Functions
- Pushing Primitive Recursion
- RM versus PR
- General Recursive Functions
- Church-Turing Thesis
Note that we never checked whether $A$ is really total.

One possible proof is by induction on $x$, and subinduction on $y$.

A more elegant way is to use induction on $\mathbb{N} \times \mathbb{N}$ with respect to the lexicographic product order

$$(a, b) < (c, d) \iff (a < c) \lor (a = c \land b < d),$$

a well-ordering of order type $\omega^2$.

Exercise

*Carry out the proof of totality.*
Can we measure the gap between p.r. and Ackermann?
How much do we have to add to primitive recursion to capture the Ackermann function?

**Proposition**

*There is a primitive recursive relation $R$ such that*

$$A(a, b) = c \iff \exists t \ R(t, a, b, c)$$

Think of $t$ as a complete trace of the computation of the Ackermann function on input $a$ and $b$. For example, $t$ could be a hash table that stores all the values that were computed during the call to $A(a, b)$ using memoizing.
More precisely, a trace for $A(a, b) = c$ is a list $t$ of triples such that

- $(a, b, c) \in t$
- $(0, y, z) \in t$ implies $z = y^+$
- $(x^+, 0, z) \in t$ implies $(x, 1, z) \in t$
- $(x^+, y^+, z) \in t$ implies $(x, u, z) \in t$ and $(x^+, y, u) \in t$ for some $u$.

Any table that satisfies these rules proves that indeed $A(a, b) = c$ (though it might have extraneous entries).

So we can primitive recursively check whether an alleged computation of $A$ is in fact correct.
So to compute $A$ we only need to add search: systematically check all possible tables until the right one pops up (it must since $A$ is total). The problem is that this search is no longer primitive recursive.

More precisely, let

$$\text{acker}(t, x, y) \iff t \text{ is a correct trace for } x, y, z$$

where $(x, y, z) \in t$

$$\text{lookup}(t, x, y) = z \iff (x, y, z) \text{ in } t$$

Then

$$A(x, y) = \text{lookup} \left( \min( t \mid \text{acker}(t, x, y) ) , x, y \right)$$

This is all primitive recursive except for the unbounded search in $\min$. 
Since the Ackermann function misses being primitive recursive only by the lack of an unbounded search operation, it is tempting to extend primitive recursive functions a bit by adding a min operator.

From the previous discussion, primitive recursive plus min operator is powerful enough to produce the Ackermann function—of course, the real question is: what is relationship between the extended class and (register-machine) computable functions in general?

As we will see, we obtain the same class of functions.
Definition

The class of general recursive functions is defined like the primitive recursive functions, but with one additional operation: unbounded search.

\[ f(x) = \min (z \mid g(z, x) = 0) \]

Here \( g \) is required to be total.

Thus, \( f(x) = 3 \) means \( g(3, x) = 0 \), but \( g(2, x), g(1, x), g(0, x) > 0 \).

**Note:** Even though we insist that \( g \) is total, \( f \) will in general be a partial function: for some \( y \) there may well be no \( z \).

But one cannot allow for \( g \) itself to be partial; there are examples that show that this would violate computability.
Other names in the literature: partial recursive functions or $\mu$-recursive functions.

The notion $\mu$-recursive function comes from the fact that in the older literature one usually finds

$$f = \mu g$$

rather than a reference to $\min$.

The notion of “general recursive function” was used because primitive recursive functions were originally referred to as “recursive functions”.

To round off the confusion, some authors mean total computable functions when they say “recursive function”, and use “partial recursive function” for the general case.

We will use the latter convention (well, most of the time anyways).
- Primitive Recursive Functions
- Pushing Primitive Recursion
- RM versus PR
- General Recursive Functions

5 Church-Turing Thesis
In the context of general computability theory “primitive recursive” translates roughly into “easily computable.”

In some theories it is convenient to assume that all primitive recursive functions and relations are simply given as atomic objects, there is no need to dig any deeper.

Of course, this has nothing to do with practical computability. Even just a handful of nested primitive recursions can well mean that the computation is not feasible.
But primitive recursive functions provide a nice framework for other models of computation.

- Define a class $C$ of possible configurations and code them up as natural numbers, so $C \subseteq \mathbb{N}$ is primitive recursive.
- Define a one-step relation on $C$ that is primitive recursive.
- Define some reasonable input/output conventions.

For example, register machines, Turing machines, random access machines, parallel random access machines all fall into this framework. Other approaches such as programming languages, equational calculi or more abstract models such as Church’s lambda calculus also fit into this framework, though not quite as easily.
The number-theoretic scenario (input and output are natural numbers).
Claim: As long as this is done in a reasonable way, we always get the same notion of computability.

Actually, Church was initially referring to the $\lambda$ calculus and general recursive functions only, but the same reasoning applies to other, now standard, models. Incidentally, Gödel was originally very hesitant to agree to Church’s Thesis; he did change his mind once he saw Turings 1936 paper.
There are several approaches towards defining computability. Different models may well turn out to be equivalent, e.g., register machine computable is the same as general recursive. Primitive recursive functions are much stronger than actually computable functions, but fail to completely capture the notion of computability. Recursive functions encapsulate the idea of unbounded search. The Ackermann function explodes at surprisingly low levels. Church’s Thesis states that various formal notions of computability precisely capture the intuitive notion of computability.
