Abstract - This paper describes mechanisms used by humans to stand on moving platforms, such as a bus or ship, and to combine body orientation and motion information from multiple sensors including vision, vestibular, and proprioception. A simple mechanism, sensory re-weighting, has been proposed to explain how human subjects learn to reduce the effects of a moving support platform on balance. Our goal is to replicate this robust balance behavior in bipedal robots. We present results exploring sensory re-weighting in humans, simulation, and in a robot implementation.

Index Terms - Balance control, posture, sensory re-weighting

I. INTRODUCTION

Humans utilize a variety of sensory systems to maintain balance, primary among them being the visual, vestibular and proprioceptive systems. Several studies have demonstrated that human standing posture is affected by perturbations to these sensory systems [1-6], suggesting that feedback control, based on perceived body motion, contributes to postural stability. There is redundancy across these sensory systems and the organization of these feedback control mechanisms is not fully known. Also, there is some question as to whether feedback alone is sufficient for human postural control [7,8], although recent studies have shown that a postural control strategy based solely on sensory feedback can account for experimental findings involving a variety of proprioceptive and visual perturbations to postural control [9,10].

A key finding of human postural control experiments has been that the integration of sensory information appears to be dynamically regulated to adapt to changing environmental conditions and the available sensory information, a process sometimes referred to as “sensory re-weighting” [2,9-15]. For example, during eyes-closed stance on a fixed, level surface, the primary sensory source for information about body orientation in space is proprioceptive, but under conditions where the platform moves, the primary source of sensory information shifts from proprioceptive to graviceptive/vestibular [9].

Current biped robots move slower than humans and are much less stable [16-21]. The control algorithms are typically not designed to handle large perturbations or

ambiguous sensory information, two components often seen in human balance experiments and daily activity. Instead, the floor is assumed to be level, stiff, and not in motion. Independent and decoupled simple linear controllers for each joint (joint-level PD control) with only proprioceptive feedback form the core of robot standing balance control, where perturbations small enough that decoupled linear control is adequate. Some robots use force control to implement a more compliant ankle [19,22,23] which is useful for stepping on uneven terrain, but not for standing vertically. There is only one response strategy to choose from, typically using ankle torques to adjust the center of pressure (the ankle strategy). One exception to this are the Honda robots, which can take a step in response to a large perturbation [19]. More advanced schemes have been proposed but not yet implemented [24-26].

We note a major difference between current robots and humans in how balance is maintained. In robotics, the emphasis has been on controlling the location of the center of pressure based on proprioception, with little use of vestibular signals and no use of vision. In humans, vestibular and visual signals are also important [9]. The multiple sensory sources allow for more complex sensorimotor strategies not seen in biped robots, and arguably contribute to robust human balance function across a variety of environments and perturbations.

II. HUMAN POSTURAL CONTROL AND SENSORY RE-WEIGHTING

Human postural control has been studied for over fifty years, with conceptual and computational models being developed. These models have led to advances in the diagnosis and management of balance disorders. A variety of models have been proposed and continue to be developed (e.g., [3,9,11,27-33]). Many models are developed in accordance with specific experimental conditions; while no single model explains all aspects of human postural control, the model [9] we consider in detail here has been shown to accurately fit experimental data in a variety of conditions, both steady-state [9] and transient [10]. Moreover, the model provides a conceptually simple, yet experimentally supported, concept of sensory adaptation / re-weighting.

The model (Figure 1) consists of a linearized (i.e., small angle) single-link inverted pendulum representation of body dynamics. Upright stance is maintained by a corrective torque applied about the ankle joint, generated by a proportional-

integral-derivative (PID) controller, with fixed gain parameters K_p , K_i and K_d . Note that the model utilizes both position and velocity information to stabilize the inverted pendulum, consistent with control theory.

The parameters K_p and K_d represent the active stiffness and damping, respectively, of the postural control system. They are termed “active” because they generate corrective torque in response to an external perturbation, in contrast to passive stiffness and damping of the muscles and tendons during quiet standing. The contributions of the passive stiffness and damping to torque generation have been found to be negligible during perturbations (a factor of ten smaller than the active torque generation) and can be dropped from the model [9,30]. The parameter t_d in the model represents the effective time delay of the system, which includes combined delays due to sensory transduction, neural transmission, nervous system processing, muscle activation, and force development.

If all of the sensory systems are modelled as having no dynamics over the bandwidth of body sway movement (i.e., taken as unity), then

$$E(t) = W_v(VS(t) - BS(t)) + W_p(SS(t) - BS(t)) - W_g(BS(t)) \quad (1)$$

For healthy subjects with intact sensory organs and perturbations limited in magnitude and bandwidth to those often used in experimental studies of human postural control (e.g., [9,10]), this “no dynamics” assumption for the sensory systems is reasonable, and simplifies the sensory integration strategy, which is modelled via the sensory weights W_v , W_g and W_p . Unlike the fixed PID gains of the controller, the sensory weights can change with environmental conditions (the “sensory re-weighting” strategy). These sensory weights represent the *relative* contribution of each sensory channel to postural control.

For the model, the body sway (BS) in response to support surface (SS) or visual scene (VS) motion is given in the Laplace domain by

$$BS(s) = H(s)[W_p SS(s) + W_v VS(s)] \quad (2a)$$

where s is the Laplace variable and

$$H(s) = \frac{(K_D s^2 + K_p s + K_I) e^{-s t_d}}{J s^3 - mgh s + \mathbf{W}(K_D s^2 + K_p s + K_I) e^{-s t_d}} \quad (2b)$$

is the unity-gain transfer function of the postural control feedback model.

A key concept of the model and the sensory re-weighting hypothesis is the *effective overall sensory weight*, \mathbf{W} , of the system, which is the sum of the sensory weights of *those channels that contribute accurate sensory information about body sway* (BS). For example, the effective overall sensory weight is $\mathbf{W} = W_p + W_g + W_v$ during eyes-open quiet standing on a fixed platform. But, for eyes-closed stance, the visual system does not contribute information about body sway, so the effective overall sensory weight in this case is $\mathbf{W} = W_p + W_g$. For stance on a sway-referenced platform, on which the support surface rotates in one-to-one proportion to body sway (SS=BS in Figure 1), the proprioceptive channel does not contribute accurate information about body sway, so in this case the effective overall sensory weight is $\mathbf{W} = W_g + W_v$. Thus, the sensory weights that contribute to the effective overall sensory weight are different under different environmental conditions (i.e., under different manipulations of the sensory inputs). An important point to appreciate is that as the value of \mathbf{W} changes, the dynamics of body sway will change. In particular, during transient conditions the system can be pushed towards instability if sensory re-weighting is inadequate, causing \mathbf{W} to be too large or too small, as discussed further below.

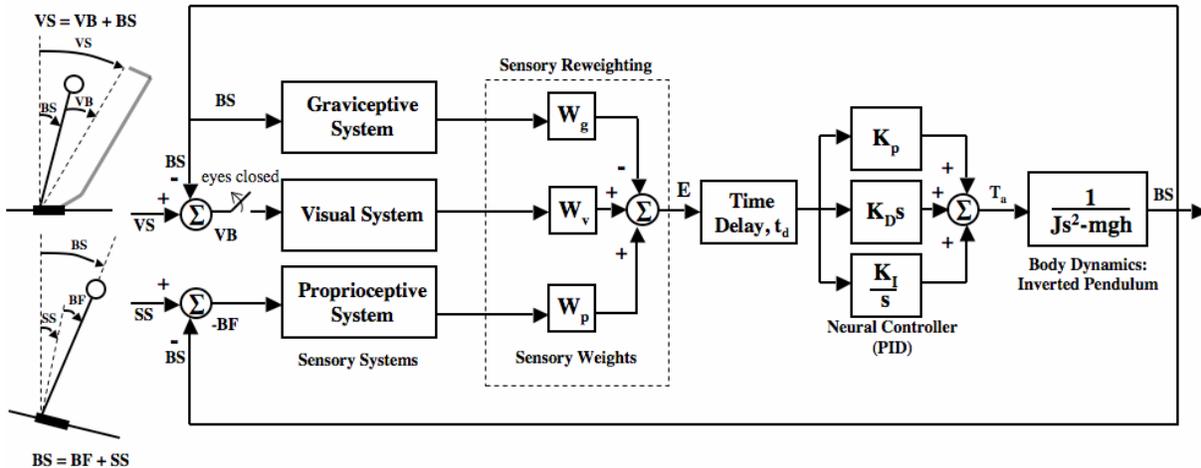

Fig. 1: Feedback model of postural control. The body is modelled as a linearized inverted pendulum. The sensory pathways include variable sensory weights (W_g , W_v , W_p) that can change as environmental factors change (the “sensory re-weighting” hypothesis). BS, VS and SS are angles, with respect to earth-vertical, of the body, visual scene and support surface, respectively, as shown in the stick-figures. VB and BF are the relative angles of the visual scene and the support surface with respect to the body. Corrective torque about the ankle, T_a , is generated by a proportional-integral-derivative (PID) controller with fixed gains K_p , K_D , K_I , acting on the combined delayed sensory error signal E . Modified from [9] and [10].

Steady-state vs. transient conditions

The sensory re-weighting hypothesis holds that, under *steady-state* conditions, the effective overall sensory weight is unity, $\mathbf{W}=1$ (this is a torque normalization constraint that results in non-oscillatory dynamics of body sway) [9]. For example, for stance with eyes closed on a fixed platform, $\mathbf{W}=W_p+W_g=1$ during steady-state. However, during *transient* conditions, in particular following a sudden change in the available sensory information, \mathbf{W} will differ from unity for a period of time until the sensory integration process adjusts the weights of the sensory systems to compensate for the transient change in sensory information [10]. For example, for the eyes-closed stance condition, if the platform suddenly transitions from fixed to sway-referenced, then the effective overall sensory weight becomes $\mathbf{W}=W_g$, and this is initially less than unity. If \mathbf{W} is not unity, then either too much or too little corrective torque will be generated and oscillatory sway will occur at specific frequencies. This oscillatory sway persists until the sensory integration process re-establishes $\mathbf{W}=1$. The tendency of a system to oscillate at a particular frequency is called “resonance” and is reflected by a peak in the system’s frequency response at that frequency; the sharper the peak, the more “resonant” is the system, meaning the stronger and more sustained are the oscillations. Increased resonance is characteristic of a system nearing instability. This effect of changes in the value of \mathbf{W} on the body sway that develops is illustrated in the frequency response magnitude plots shown in Figure 2. Note that the model predicts oscillatory body sway at specific frequencies if sensory re-weighting is inappropriate (\mathbf{W} less than or greater than one).

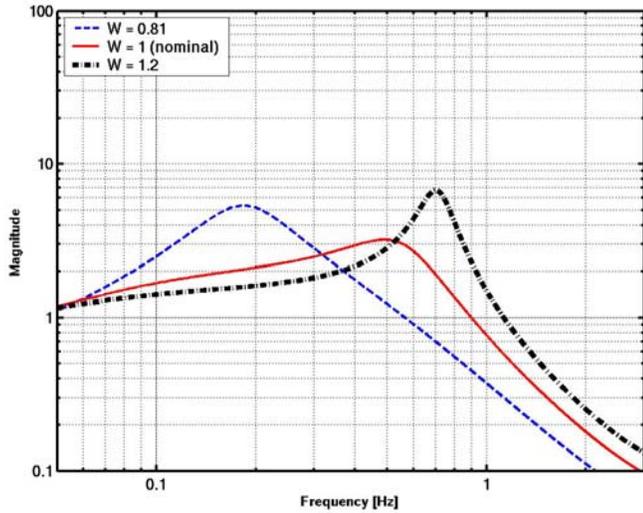

Fig. 2: Frequency response plots for the postural control model in Figure 1, showing the effects of changes in the effective overall sensory weight, \mathbf{W} . Dotted curve is for $\mathbf{W}=0.81$, solid is for $\mathbf{W}=1$, dotted-dashed is for $\mathbf{W}=1.2$. PID control parameters were the same in all cases [$K_p=18.1$ N-m/deg, $K_I=2.2$ N-m/deg-s, $K_D=6.1$ N-m-s/deg], as were other physical parameters [$g=9.8$ m/s², $m=83$ kg, $h=0.9$ m, $J=81$ kg-m²]. Note the changes in the frequency response as \mathbf{W} changes, and in particular the development of resonances (peaks in the frequency response) at particular frequencies for $\mathbf{W}>1$ and $\mathbf{W}<1$.

III. EXPERIMENTAL RESULTS: SENSORY RE-WEIGHTING IN HEALTHY YOUNG ADULTS

Under experimental conditions where the sensory input to the postural control system was deliberately altered, transient periods of low or high frequency oscillations in the body sway of healthy young adults were observed [10], consistent with the oscillations predicted by the frequency response of the model (Figure 2). Shown in Figure 3 (left) are body sway measurements and the corresponding time-varying spectrum (or time-frequency distribution) obtained during eyes-closed stance on a platform that transitioned from fixed, to sway referenced for 60 seconds (labelled SR in Figure 3), and then back to fixed. (See [10] for details of the experimental protocol, methodology and data analysis.) During the initial period of eyes-closed stance on the fixed platform, the effective overall sensory weight is $\mathbf{W}=W_p+W_g$, and under the sensory re-weighting hypothesis, once steady-state has been reached we have $W_p+W_g=1$. Following the transition to the sway-referenced platform (starting at 60 seconds in the figure), the proprioceptive channel no longer provides accurate information about body sway. Hence the effective overall sensory weight becomes $\mathbf{W}=W_g$ which will be less than unity immediately after the transition to sway-referencing. This decrease in the value of \mathbf{W} will cause a change in the frequency characteristics of body sway as predicted by the frequency response curve in Figure 2 (dashed curve) and seen experimentally in the time-varying spectrum of Figure 3 (left; note the band of energy in the TFD plot around 0.1 Hz that develops after $t=60$ s). As the body adjusts to the sway-referenced condition over time, sensory re-weighting brings the effective sensory weight back to unity, i.e., the graviceptive weight W_g increases to near unity. Upon the transition back to a fixed platform (at $t=120$ sec), the effective sensory weight becomes $\mathbf{W}=W_p+W_g$, but now the graviceptive weight is higher than it was during the initial fixed platform condition ($t < 60$ s), so that now $\mathbf{W}>1$. According to the model, this should result in oscillatory sway near 1 Hz (Figure 2, dot-dashed curve), which was observed experimentally (see the time-varying spectrum in Figure 3 (left) and in particular the band of energy that develops around 1 Hz after $t=120$ s). A simulation from the model of these experimental conditions and postulated sensory re-weighting is shown in Figure 3 (right). The good match between model predictions and experimental results inspires some confidence that the model captures important attributes of sensorimotor integration in postural control.

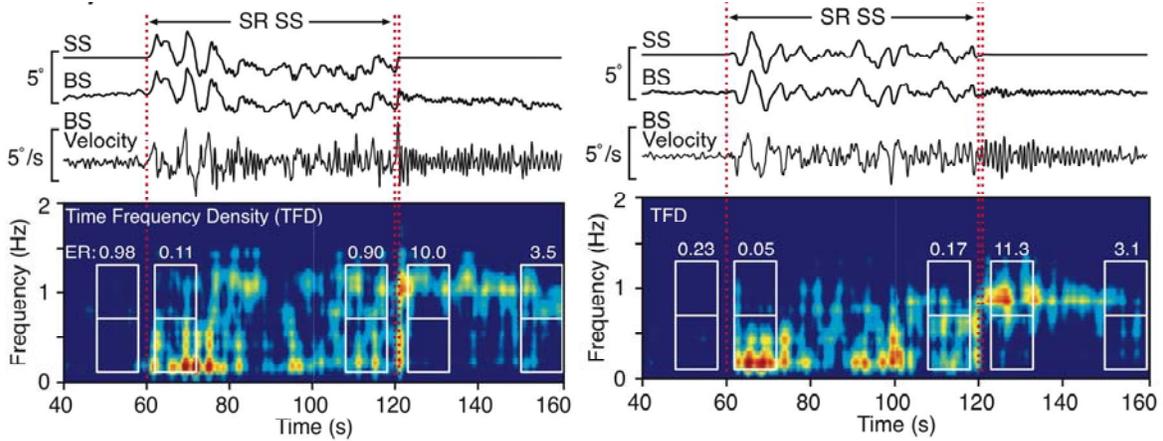

Fig 3: Time series and corresponding time-varying spectra (or time-frequency distributions (TFD), bottom plots) of postural sway from a subject (LEFT) and from the model (RIGHT). The support surface angle (SS) is sway-referenced (SR) during the period 60-120 s. After rapidly returning to a fixed support surface within 1 s (denoted by the double vertical dotted lines at 120 s), body sway oscillations at ~ 1 Hz develop (orange-yellow band in the TFD around 1 Hz for $t > 120$ s), indicative of inadequate sensory re-weighting. (Boxed areas in the TFD correspond to time-frequency regions of interest for which energy ratios (ER) of high-frequency (0.7-1.3 Hz) to low-frequency (0.1-0.7 Hz) energy were analysed; numbers above the box reflect the ER values.) Adapted from [10].

IV. EXPERIMENTAL ROBOTIC CONTROL UTILIZING MANUAL SENSORY RE-WEIGHTING

We have implemented a preliminary sensory re-weighting control strategy similar to that described in [9,10] in a biped robot. This preliminary implementation used the robot sensors directly, rather than attempting to simulate biological signals. To test the model, the robot was placed on a standard clinical balance testing platform (Figure 4), and controller gains were set to maintain stability, with proprioceptive (ankle angle) and graviceptive (inertial) sensory weights initially set to 0.6 and 0.4, respectively (Figure 4 right). The proprioceptive and graviceptive gains are consistent with reports in the literature that during quiet standing with eyes closed, proprioception seems to be the dominant source of sensory information for

standing balance in humans.

The platform is initially fixed, and at a certain point (10 seconds in Figure 4) begins sway referencing: rotating in direct 1:1 proportion to body angle about an axis collinear with the ankle joint of the robot. This behaviour has the effect of eliminating reliable ankle proprioception, because the ankle angle remains at approximately 90 degrees, independent of body sway. A feedback control strategy that utilizes primarily ankle proprioception would result in the robot falling shortly after the platform transitions to the sway-referenced condition, as indeed occurred when re-weighting was not used (Figure 4). We note that it is not unusual for human subjects to also lose their balance the first time they experience a sway-referenced platform with eyes closed.

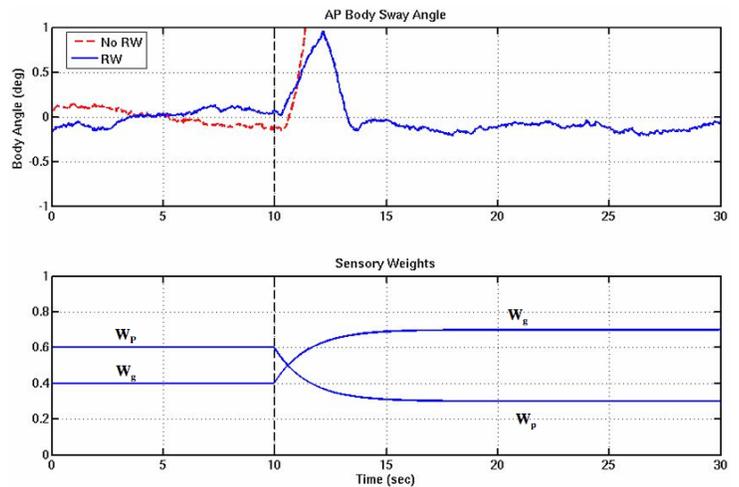

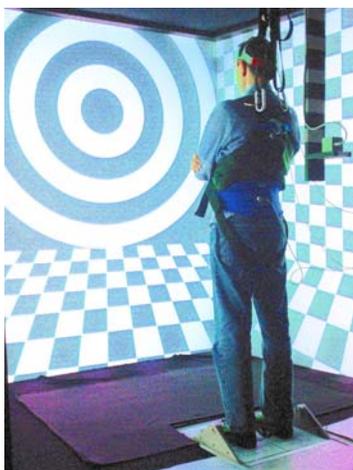

Fig. 4: Left: An experimental subject standing on a clinical balance platform (Equitest) in a visual “cave”. Middle: Our bipedal robot standing on an identical balance platform. Right: Preliminary results on robot balancing during sway referencing, which tilts the support platform to keep the ankle angle at 90° . The top graph plots body angle in two trials, and the vertical dashed line indicates the onset of sway-referencing. The first trial (dashed red line) is with fixed feedback gains, and the robot quickly falls. The second trial (solid blue line) is with sensory re-weighting where the weight on the now misleading ankle sensor is reduced. The bottom graph plots the manually specified sensor weightings for proprioception (W_p) and graviception (W_g) during sensory re-weighting. When sensory re-weighting is not used the weights are held constant at their initial values (0.6, 0.4).

To maintain balance, the source of sensory information must be rapidly switched from ankle proprioception to the graviceptive sensors, which provides a measure of body angle with respect to earth vertical. We manually implemented sensory re-weighting in the robot model, so that at the transition of the platform from fixed to sway-referenced, the graviceptive gain increased and the proprioceptive ankle gain decreased. This strategy resulted in stable stance for the robot on the sway-referenced platform (Figure 4). Thus, we have demonstrated that sensory re-weighting is a feasible control solution that can be implemented on a physical system with its real world noise and unmodelled dynamics.

V. BALANCE CONTROL IN AN OPTIMIZATION CONTEXT

In this section we put sensory re-weighting in an optimal filtering and control context, to lay the groundwork for future *automatic* sensory re-weighting. Figure 5 is a block diagram of a linear quadratic Gaussian (LQG) model for standing balance in a humanoid robot. For simplicity, the robot dynamics are modelled as a single link inverted pendulum, where the states (angle and angular velocity) of the inverted pendulum are defined with respect to vertical. To maintain an upright position a controlling torque (u_c) is applied at the ankle joint. The torque is generated by state feedback $u_c = -K\hat{x}$, where K is the state feedback gain matrix and \hat{x} is the state estimate. The state feedback gain is designed to match the natural frequency ($\omega_n=2$) and damping ratio ($\zeta=1$) found in human experiments [9]. The robot's mass multiplied by the height of its center of mass is $ml_{cm}=34.29$ Kg-m, and its moment of inertia about the ankle is $J=52.39$ Kg-m². The position and velocity gains are given by:

$$K_p = \omega_n^2 J + ml_{cm} g \quad (3a)$$

$$K_D = 2\zeta\omega_n J \quad (3b)$$

resulting in $K = [551.3 \quad 225.4]$.

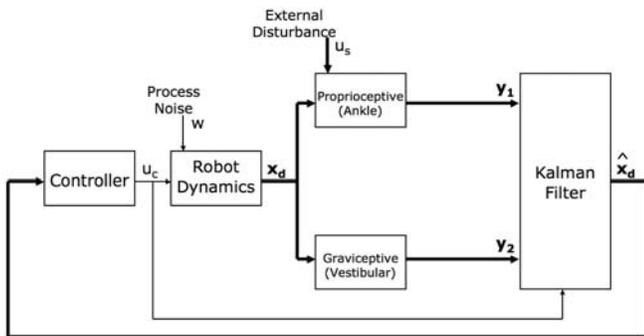

Fig. 5: Linear quadratic Gaussian model for standing balance, where vector elements are represented by bold letters and lines. The robot dynamics are modeled as a single-link inverted pendulum. The model includes two sensory channels, namely the proprioceptive (ankle) and graviceptive (vestibular), where both channels are assumed to sense position and velocity. The ankle torque u_c is generated by state feedback. State estimates are obtained from a Kalman filter.

State estimates are obtained from a Kalman filter, where the inputs are the noisy sensory channels as well as the ankle torque (Figure 5). The model includes two sensory channels: the proprioceptive (ankle) and graviceptive (vestibular) channels. It is assumed that each sensory channel senses both position and velocity of the robot and that the channels have no dynamics over the bandwidth of body sway movement. To simulate spontaneous sway, we have included process noise (w) with variance $Q_w=.002$. To perturb the proprioceptive sensory system we have included an external disturbance u_s which moves the foot. Since we model the ankle as a pure torque source, this perturbation does not affect the body directly, but only affects the proprioceptive measurement of joint angle and joint angular velocity.

To design the Kalman filter, the covariance on the sensor noise is:

$$R_{L_1} = \begin{bmatrix} \mathbf{0.14} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0.14} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{65} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0.21} \end{bmatrix} \quad (4)$$

where the noise covariance for the graviceptive channel is as reported in [11]. This leads to Kalman filter gains of

$$L_1 = \begin{bmatrix} \mathbf{0.0043} & \mathbf{0.0110} & \mathbf{0.0000} & \mathbf{0.0073} \\ \mathbf{0.0110} & \mathbf{0.0278} & \mathbf{0.0000} & \mathbf{0.0185} \end{bmatrix} \quad (5)$$

We choose the ratio of the velocity elements of R to get a ratio of 60/40 in the proprioceptive vs. graviceptive elements of L_1 , which roughly matches human sensor weightings [9]. We have found that scaling R as a whole has little effect on the Kalman filter gains, probably due to the fact that the controlled system is unstable. To handle proprioceptive perturbations, we design a second Kalman filter with sensor noise covariance and gains:

$$R_{L_2} = \begin{bmatrix} \mathbf{0.49} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0.49} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{65} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0.21} \end{bmatrix} \quad (6)$$

$$L_2 = \begin{bmatrix} \mathbf{0.0023} & \mathbf{0.0057} & \mathbf{0.0000} & \mathbf{0.0134} \\ \mathbf{0.0057} & \mathbf{0.0145} & \mathbf{0.0000} & \mathbf{0.0339} \end{bmatrix} \quad (7)$$

In this case the estimate of the strength of proprioceptive sensor noise was increased, so that the ratio of proprioceptive to graviceptive velocity elements in L is roughly 30/70, matching human sensor weightings during ankle perturbations.

We now present a simulation for the model described above. The external disturbance (platform perturbation) applied to the ankle has a total duration of 181 seconds and consists of two cycles of a pseudorandom ternary sequence (PRTS: random sequence of 0,-n,+n) preceded and followed by 30 seconds of no disturbance (Figure 6). Each cycle of the PRTS is 60.5 seconds with a 2-degree peak-to-peak amplitude. The body sway angle resulting from the external disturbance to the model is plotted in Figure 7, where the vertical black dashed line indicates onset of sensory re-weighting (switching Kalman filter gains from L_1 to L_2). As evident from the graph, after about 70 seconds into the perturbation, where sensory re-weighting has occurred, the model is able to lower the amount of body sway and rely more on the less noisy channels available.

Figure 8 shows this experiment applied to the robot. The gains had to be changed slightly from the simulation to compensate for additional damping in the actuation and other unmodelled dynamics $K = [700,150]$. We see that Figures 7 and 8 show similar performance improvements due to sensory re-weighting.

VI. DISCUSSION

We have described our work in modelling human balance control, and preliminary work applying sensory re-weighting to robots. Our long term goal is to develop computational theories of how the weights in sensory re-weighting are chosen. Models of this process are conspicuously absent from work on human balance control, and are necessary for robot balance control.

One lesson from human balance control is that sensory re-weighting is a simple mechanism to handle a wide variety of perturbations: standing on a moving bus, watching a moving scene, or handling the effects of self motion on inertial sensing. Different sensory channels are more or less sensitive to different types of perturbations, and thus different types of perturbations can be compensated for by weighting the various sensory channels. An accurate model of the disturbance, sensors, or dynamics of the system is not needed. For example, it is not necessary to accurately estimate the platform angle in order to stand during ankle perturbations.

Sensory re-weighting provides a way to combine many sensory systems. Humans use proprioception, inertial sensing, and vision to stand robustly. Robots typically rely on only one or two sensory systems. Another function of sensory re-weighting is to handle inconsistent or malfunctioning sensors. An important step towards robust robot behaviour is developing mechanisms to handle erroneous, inconsistent, or malfunctioning sensors.
