Abstract

The Dynamic Optimality Conjecture [ST85] states that splay trees are competitive (with a constant competitive factor) among the class of all binary search tree (BST) algorithms. Despite 20 years of research this conjecture is still unresolved. Recently, Demaine *et al.* [DHIP04] suggested searching for alternative algorithms which have small but non-constant competitive factors. They proposed *Tango*, a BST algorithm which is nearly dynamically optimal – its competitive ratio is $O(\log \log n)$ instead of a constant. Unfortunately, for many access patterns, such random and sequential, *Tango* is worse than other BST algorithms by a factor of $\log \log n$.

In this paper, we introduce the multi-splay tree (MST) data structure, which is the first BST to simultaneously achieve $O(\log n)$ amortized, $O(\log^2 n)$ worst-case, and $O(\log \log n)$ -competitive costs for a sequence of queries. We also prove the sequential access lemma for MSTs, which states that sequentially accessing all keys takes linear time. Thus, MSTs are $O(\log \log n)$ -competitive like *Tango* but, unlike *Tango*, require only $O(\log n)$ amortized time per access in an arbitrary sequence and only $O(1)$ amortized time per access during sequential access sequence.

Furthermore, we generalize the standard framework for competitive analysis of BST algorithms to include updates (insertions and deletions) in addition to queries. In doing so, we extend the lower bound of Wilber [Wil89] and Demaine *et al.* [DHIP04] to handle these update operations. We show how MSTs can be modified to support these update operations and be $O(\log \log n)$ -competitive in the new framework while maintaining the rest of the properties above.

1 Introduction

A splay tree [ST85] is a self-adjusting form of binary search tree where each time a node in the tree is accessed, that node is moved to the root according to an algorithm called *splaying*. In a splay tree, all accesses and updates (e.g. insert, delete, join, split) are accomplished by using the splaying algorithm. Splay trees have been shown to have a number of remarkable properties, including the Balance Theorem [ST85], the Static Optimality Theorem [ST85], the Static Finger Theorem [ST85], the Working Set Theorem [ST85], the Scanning Theorem [Sun89], the Sequential Access Theorem [Tar85, Sun92, Elm04], and the Dynamic Finger Theorem [CMSS00, Col00].

The Dynamic Optimality Conjecture [ST85] states that on any sequence of accesses, the cost of splay trees on that sequence is within a constant factor of any other BST algorithm for processing that sequence of accesses. All of the properties of splay trees cited in the above paragraph are special cases of Dynamic Optimality. Dynamic Optimality is equivalent to the statement that splay trees are c -competitive [ST85] for some constant c . Resolving this conjecture seems difficult – it has defied concerted attempts to solve it for about 20 years.¹

Demaine *et al.* [DHIP04] suggested searching for alternative binary search tree algorithms that have small but non-constant competitive factors. They proposed *Tango*, a BST algorithm that achieves dynamic optimality with a competitive ratio of $O(\log \log(n))$. They achieved this ratio by making use of Wilber’s first lower bound on the cost of an access sequence [Wil89].

We introduce the multi-splay tree (MST) data structure.² In addition to being $O(\log \log n)$ -competitive, MSTs also simultaneously achieve $O(\log n)$ amortized and $O(\log^2 n)$ worst-case costs for sequences of queries. We also prove the sequential access lemma for MSTs, which states that sequentially accessing all keys takes linear time. Although MSTs are quite similar to *Tango*, they do achieve improved performance in several ways. *Tango* does not have the sequential access property, nor does it achieve $O(\log n)$ amortized cost per operation.³

The framework in which the $O(\log \log n)$ -competitive bounds for *Tango* and MSTs are proven does not allow for insertions or deletions. We generalize this framework to include these update operations, and extend the lower bound appropriately. We also show how to modify the MST data structure to handle insertions and deletions, and prove that it remains $O(\log \log n)$ -competitive while preserving the rest of the properties mentioned above.

1.1 Model

In order to discuss optimality of BST algorithms, we need to give a precise definition for this class of algorithms, and their costs. The model we use is that implied by Sleator and Tarjan [ST85] and developed in detail by Wilber [Wil89]. A static set of n keys is stored in the nodes of a binary tree. The keys are from a totally ordered universe, and they are stored in symmetric (left to right) order. Each node has a pointer to its left child, to its right child, and to its parent. Also, each node may keep a constant⁴ amount of additional information but no additional pointers.

The BST algorithm is required to process a sequence of queries $\sigma = \sigma_1, \dots, \sigma_m$. Each access σ_i is a query to a key $\hat{\sigma}_i$ in the tree⁵, and the requested nodes must be accessed in the specified order. Each access starts from the root and follows pointers until the desired node (the one with key $\hat{\sigma}_i$) is reached. The algorithm is allowed to update the fields and pointers in any node that it touches along the way. The cost of the algorithm to satisfy the sequence of queries is defined to be the number of nodes that it touches. Finally, we do not allow any information to be preserved from one access to the next, other than in the nodes’ fields, and a pointer to the root of the tree. It is easy to see that this definition is satisfied by any of the standard BST algorithms, such as red-black trees and splay trees.

This model does not handle insertions and deletions, but we generalize it to handle insertions and deletions in Section 6.

¹It is even apparently difficult to obtain any (online exponential time [BCK02] or offline polynomial time) binary search tree algorithm which is c -competitive.

²Throughout this paper, MST always means multi-splay tree and not minimum spanning tree.

³For example, on a random access pattern, *Tango* uses worst-case $\Theta(\log n \log \log n)$ time per query. However, it has been pointed out that *Tango* can be modified to achieve $O(\log n)$ amortized performance, at a cost of changing the worst-case to $\Theta(n)$.

⁴To be consistent with standard conventions, here we consider $O(\log n)$ bits to be “constant.”

⁵This model is only concerned with successful searches.

1.2 Interleave Lower Bound

Given an initial tree T_0 and an m -element access sequence σ , for any BST algorithm satisfying these requests there is a cost, as defined above. Thus, we can define $\text{OPT}(T_0, \sigma)$ to be the minimum cost of any BST algorithm for satisfying these requests starting with initial tree T_0 . Wilber [Wil89] derived a lower bound on $\text{OPT}(T_0, \sigma)$, and this was rephrased and renamed the *interleave bound* by Demaine *et al.* [DHIP04].

Let $\text{IB}(P, \sigma)$ denote the interleave lower bound on the cost of accessing the sequence σ , where P is a BST (later called a *reference tree*) over the same set of keys as T_0 . Define $\text{IB}(P, \sigma) = \sum_{v \in P} \text{IB}(P, \sigma, v)$, where for each node v , $\text{IB}(P, \sigma, v)$ is defined as follows. First, restrict σ to the set of nodes in the subtree of P rooted at v (including v). Next, label each access in this restricted σ as either “left” (or “right”) depending on whether the accessed element is in the left subtree (including v) or right subtree of v . Now, $\text{IB}(P, \sigma, v)$ is the number of times the labels switch.

Theorem 1. [Wil89, DHIP04] $\text{OPT}(T_0, \sigma) \geq \text{IB}(P, \sigma)/2 - O(n) + m$

Culik and Wood [CW82] proved that the number of rotations needed to change any binary tree of n nodes into another one is at most $2n - 2$.⁶ It follows that $\text{OPT}(T_0, \sigma)$ differs from $\text{OPT}(T'_0, \sigma)$ by at most $2n - 2$. Thus, as long as $m = \Omega(n)$, the initial tree is irrelevant. We shall make this assumption.

1.3 The Access Lemma for Splay Trees

Sleator and Tarjan [ST85] proved that the amortized cost of splaying a node is bounded by $O(\log n)$ in a tree of n nodes. By the use of the flexible potential described below, they proved tighter bounds on the amortized cost of splaying for access sequences that are non-uniform (e.g., the Static Optimality Theorem). This framework is essential for the analysis of multi-splay trees.

For an arbitrary positive weight function w over the nodes of a splay tree, they defined the size $s(v)$ of node v to be $\sum_{v \in \text{subtree}(v)} w(v)$, the sum of the weights of all nodes in v 's subtree. They defined the potential of the tree to be $\sum_{v \in V} \lg s(v)$, where V is the set of nodes in the splay tree.

As a measure of the cost (running time) of a splaying operation, they used the distance from the node being splayed to the root of the tree (except when the node is the root, in which case the cost is 1). With these definitions, Sleator and Tarjan proved the following theorem about the amortized cost of splaying.

Theorem 2. (*Access Lemma*) [ST85] *The amortized time to splay a node v in a tree currently rooted at r is at most $O(1 + \lg(s(r)/s(v)))$.*

Theorem 3. (*Generalized Access Lemma*) *Given a pointer to an ancestor node a , the amortized time to splay a node v with respect to an ancestor a in the same splay tree is at most $O(1 + \lg(s(a)/s(v)))$.*

The main difference between this and the original access lemma is that we are allowed to stop at any ancestor a . Its truth follows from the proof of the original access lemma because that proof does not require splaying to go all the way to the root.

2 The Multi-Splay Tree Data Structure

Consider a *balanced*⁷ BST P made up of n nodes, which we will refer to as the *reference tree*. Because P is balanced, the depth of any node in P is at most $2 \lg(n + 1)$. (The depth of the root is defined to be 1.) Each node in the reference tree has a *preferred child*. The structure of the reference tree is static (but we will generalize it to support insert and delete in Section 6), except that the preferred children will change over time, as explained below. We call a chain of preferred children a *preferred path*. The nodes of the reference tree are partitioned into approximately $n/2$ sets, one for each preferred path. The reference tree is not explicitly part of our data structure, but is useful in understanding how it works.

A multi-splay tree is a BST T (over the same set of n keys contained in the reference tree P) that evolves over time, and preserves a tight relationship to the reference tree. Each edge of a multi-splay tree is either *solid* or *dashed*. We call a set of vertices connected by solid edges a *splay tree*. There is a one-to-one correspondence between the splay trees of a multi-splay tree and the preferred paths of its reference tree. The set of nodes in a splay

⁶Sleator, Tarjan and Thurston [STT86] subsequently showed that only $2n - 6$ rotations (for $n \geq 10$) are necessary.

⁷By “balanced” we mean that every subtree t has height at most $2 \lg(|t|)$

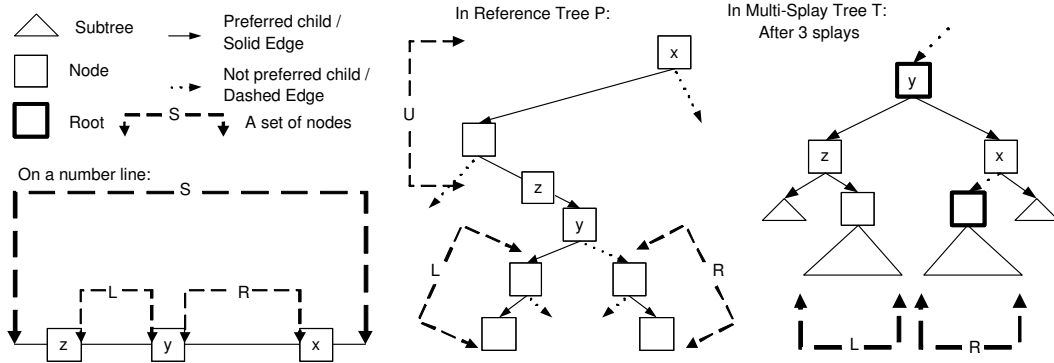

Figure 1: Graphical representations of S , U , L , R , x , y , and z during a single switch.

tree is exactly the same as the set of nodes in its corresponding preferred path. In other words, at any point in time a multi-splay tree can be obtained from its reference tree by viewing each preferred edge as solid, and doing rotations on only the solid edges. An example of P and T is shown in Figure 6 in the appendix.

Each node of a multi-splay tree T has several fields in it, which we enumerate here. First of all, it has the usual *key* field, and pointers *leftChild*, *rightChild*, and *parent*. Although the reference tree P is not explicitly represented in T , each node stores information related to P . In each node's *refDepth* field, we keep its depth in P .⁸ Note that every node in the same splay tree has a different depth in P . In addition, each node v stores the minimum depth of all of the nodes in $splaySubtree(v)$ in its *minDepth* field ($splaySubtree(v)$ contains all of the nodes in the same splay tree as v that have v as an ancestor, including v). Finally, to represent the solid and dashed edges, each node has an *isRoot* boolean variable that indicates if the edge to its parent is dashed.

3 The Multi-Splay Algorithm

Although our data structure and algorithm are simple, there are subtle details that must be correct to make the running time analysis work. In this section, we first explain the algorithm assuming we have the reference tree P , then we explain how to implement the corresponding operations in our actual representation T .

As stated above, the preferred edges in P evolve over time. A *switch* at a node just swaps which child is the preferred one. For each access, switches are carried out, from the bottom up, so that the accessed node v is on the same preferred path as the root of P . In addition, one last switch is carried out on the node that is accessed.

In other words, traverse the path from v to the root doing a switch at each non-preferred child on the path, and then finally switch v . That is the whole algorithm from the point of view of the reference tree. The tricky part is to do it without the reference tree.

Remark. If the multi-splay algorithm did not make the final switch on the queried node, the number of switches that occur in the reference tree due to a single query would be the increase in interleave bound due to that query (and with the extra switch, the amortized number of switches only increases by at most 2 per query).

Unfortunately, P is not our representation, T is. To achieve $O(\log \log n)$ -competitiveness, we can only afford to spend $O(\log \log n)$ amortized time per switch. It turns out that we can simulate a switch in P with at most three splay operations, and two changes of *isRoot* bits in T .

More specifically, suppose we want to switch y 's preferred child from left to right. To understand the effect of this, temporarily make both children of y preferred. Now, consider the set S of nodes in P reachable from y using only preferred edges. This set can be partitioned into four parts: L , those nodes in the left subtree of y in P ; R , those nodes in the right subtree of y in P ; U those nodes above y in P ; and y . When set S is sorted by key, L and R form contiguous regions, separated by y (See Figure 1).

Let us see what this means in a multi-splay tree T . The splay tree in T containing y consists of nodes $L \cup U \cup \{y\}$. After the switch it consists of $R \cup U \cup \{y\}$. To do this transformation we need to remove L and add in R . Because

⁸Note that this quantity is static in our initial description of multi-splay trees, but becomes dynamic in Section 6 when we extend multi-splay trees to support insert and delete.

L and R are contiguous regions in the symmetric ordering, we can use splaying to efficiently split off the tree containing L by splaying y and then splaying l , the leftmost node in L (stopping at the left child of y). This node, l , is the leftmost node deeper (in P) than y . We could find this in T if we had a *maxDepth* field instead *minDepth*. Adding R is done simply by setting *isRoot* to false for the node that is the lowest common ancestor of the set R in T .⁹ This method would then be analogous to the technique used by Demaine *et al.* [DHIP04].

Unfortunately, this technique does not suffice to prove the $O(\log n)$ amortized bound. To obtain the desired bound, we can only afford to splay nodes that are in $\{y\} \cup U$. We first find z , the predecessor of L in S , using the *minDepth* field. Then, we splay y and splay z until it becomes the left child of y . This ensures that the right child of z is the lowest common ancestor of L . Thus, we mark the right child of z as a root. This is equivalent to removing L from y 's splay tree. As for merging R , we simply splay the successor of y (called x) in U to be the right child of y , so that unmarking the left child of x merges in R .

However, an access is not just a single switch in P , it is a sequence of switches. For the purposes of our running time analysis, we do these from bottom to top. Also, we switch the accessed node after all the switches to pay for the traversal from the root of T to the accessed node. Notice that this final switch brings the accessed node to the root of T .

This description has glossed over a number of subtle details, like how to determine if the switch is from left-to-right or from right-to-left. In addition, we have not discussed the boundary cases such as when z or x does not exist.

In more detail, when serving a query σ_i for key $\hat{\sigma}_i$, we traverse the MST T to find $\hat{\sigma}_i$. As we traverse, we maintain $v_j = \text{predecessor}(\hat{\sigma}_i)$ and $w_j = \text{successor}(\hat{\sigma}_i)$ for the j^{th} splay tree encountered. Notice that the switch in the j^{th} splay tree must occur at the deeper of v_j and w_j in the reference tree (this is where the access path in the reference tree diverges from the preferred path corresponding to the j^{th} splay tree). Let α_j be the node we switch, and β_j be the other node. To decide the direction of the switch, observe that if $\alpha_j < \beta_j$, we switch left-to-right. Otherwise, we switch from right-to-left. After we finish all these switches from the bottom up, we make a final switch on $\hat{\sigma}_i$.

4 Running Time Analysis for an Arbitrary Sequence

We continue to use notation we have defined earlier, and for the reader's convenience we include a list of most of this paper's notation in the appendix.

For the purpose of analysis, we define the potential of a multi-splay tree T as follows. If each node v has an arbitrary positive *weight* $w(v)$, define the *size* $s(v)$ of node v to be $\sum_{v \in \text{splaySubtree}(v)} w(v)$ (i.e., the sum of the weights of all descendants of v in T reachable by traversing only solid edges). Define the potential of the tree to be $\sum_{v \in T} \lg s(v)$.

Theorem 4. *For any query in a multi-splay tree, the worst-case cost is $O(\log^2 n)$.*

Proof: This follows from the fact that to query a node, we visit at most $O(\text{height}(P))$ splay trees (because the number of switches we perform is $O(\text{height}(P))$). Because the size of each splay tree is $O(\log n)$, the total number of nodes we can possibly visit is $O(\log^2 n)$. \square

Theorem 5. *For an arbitrary access sequence $\sigma = \sigma_1 \cdots \sigma_m$ in a multi-splay tree with n elements, the cost of σ is $O(n + \text{OPT}(\sigma) * \log \log n)$.*

Proof: The total number of switches in a multi-splay tree during σ is at most $IB(P, \sigma) + 2m$ [DHIP04] (the extra $2m$ term results from the additional switch on $\hat{\sigma}_i$, which may need to be undone later in the access sequence), so it suffices to show that the amortized cost of each switch is $O(\log \log n)$.

Each switch at an arbitrary node y (with corresponding x and z) consists of up to 3 splays followed by up to 2 root markings (one node is marked as a root, another is unmarked). To analyze the amortized cost of each of these operations, we invoke the access lemma for splay trees, and recall that it uses the following potential function for a splay tree T_S : $\sum_{v \in T_S} \log s(v)$. The analysis in this sub-section assumes uniform constant weights are used for all nodes in all splay trees comprising a multi-splay tree.

⁹If the node y has one child, then that child is always the preferred child. A switch on y still induces the corresponding splays, but no root marking will occur.

The amortized cost of each of the 3 splays is $O(\log s(r))$, where r is the root of the splay tree corresponding to y 's path in the reference tree. Because $s(r) = O(\log n)$, the amortized cost of the 3 splays is $O(\log \log n)$.¹⁰

The amortized cost of marking $child(z)$ (if it exists) is $O(1)$ because it does not increase the size of any subtrees in any splay trees, so the overall potential does not increase. The amortized cost of unmarking $child(x)$ (if it exists) is $O(\log \log n)$ because the only nodes whose size increase are x and y , and the increase in each of their sizes is bounded by the size of the splay tree rooted at $child(x)$, which is $O(\log n)$.

To summarize, the amortized cost of each switch is:

$$\begin{aligned} \text{Amortized cost} &= \text{cost of splays} + \text{root marking cost} + \text{root unmarking cost} \\ &= O(\log \log n + 1 + \log \log n) \\ &= O(\log \log n). \end{aligned}$$

□

Theorem 6. *Each query σ_j in a multi-splay tree costs $O(\log n)$ amortized time.*

Proof: To analyze the amortized cost of an access in a multi-splay tree T , we assign a weight to each node in T according to its depth in the reference tree as follows: $w(v) = 2^{-\text{refDepth}(v)}$. One key fact to notice is that this implies that the sum of the weights on a path to a leaf from v (but not including it) is less than $w(v)$.

Again, each switch during an access consists of at most 3 splays, and at most 2 changes in root markers (one node is marked as root if it exists, and another is unmarked if it exists). Because the amortized cost of a splay is $O(\log(s(r)/s(v)))$ when v is being splayed in a tree rooted at r , the cost of the 3 splays is at most

$$\log(s(r_i)/s(y_i)) + \log(s(r_i)/s(x_i)) + \log(s(r_i)/s(z_i)),$$

where y_i is i^{th} node being switched going up the multi-splay tree access path to the root of the multi-splay tree and r_i is the root of the splay tree containing y_i (y_1 is the first node switched, and by convention the splay tree rooted at r_0 contains $\hat{\sigma}_j$).

Now, notice that because the elements in the splay tree rooted at r_{i-1} comprise a path to a leaf in the reference tree starting below y_i , we have $s(y_i) \geq w(y_i) > s(r_{i-1})$. Moreover, because x_i and z_i are ancestors of y_i in the reference tree, $w(x_i)$ and $w(z_i)$ are both larger than $w(y_i)$ (and, hence, $s(r_{i-1})$). Therefore, the amortized cost of splaying x (similar math applies to y and z) is

$$\sum_{i=1}^k \lg \left(\frac{s(r_i)}{s(x_i)} \right) \leq \sum_{i=1}^k \lg \left(\frac{s(r_i)}{w(x_i)} \right) \leq \sum_{i=1}^k \lg \left(\frac{s(r_i)}{w(y_i)} \right) \leq \sum_{i=1}^k \lg \left(\frac{s(r_i)}{s(r_{i-1})} \right) \leq \lg \left(\frac{s(r_k)}{s(r_0)} \right).$$

Next, we account for the cost of marking and unmarking the root bits of $child(z_i)$ and $child(x_i)$ respectively. First, notice that marking $child(z_i)$ as a root reduces the overall potential of the collection of splay trees, so it has $O(1)$ amortized cost per switch. Second, notice that unmarking $child(x_i)$ only increases $s(x_i)$ and $s(y_i)$ by at most $w(y_i)$ because the nodes of the tree rooted at $child(x_i)$ make up a path to a leaf in the reference tree starting below y_i . Thus, $s(x_i)$ and $s(y_i)$ at most double because $s(y_i) > s(x_i) \geq w(x_i) > w(y_i)$, and potential increases by at most 2. There are $O(\text{height}(P))$ switches per access, so the total cost of root marking/unmarking per access is $O(\log n)$ because the reference tree is balanced.

Finally, note that the last switch (on the accessed node) costs $O(\log(s(r_k)/s(\hat{\sigma}_j)))$. Because the smallest weight in the tree is at least $2^{-\text{height}(P)}$, and the largest size is at most 1, the total amortized cost of each access is,

$$\begin{aligned} \text{Cost} &= \text{Cost of } k \text{ switches} + \text{Cost of root markings} + \text{Cost of final switch} \\ &= O(\log(s(r_k)/s(r_0)) + \text{height}(P) + \log(s(r_k)/\log s(\hat{\sigma}_j))) \\ &= O(\log(1/2^{-\text{height}(P)}) + \text{height}(P) + \log(1/2^{-\text{height}(P)})) \\ &= O(\log n). \end{aligned}$$

□

To further generalize the above proofs, we define $\text{descendants}(v, P)$ to be all the descendants of v in P . We also define $\text{paths}(v, P)$ to be the set of all paths from a node v in P to any descendant leaf.

¹⁰As a caveat, we note that determining whether z and x exist can be done in constant time, and if they do exist the cost of finding z and x (and also y) is proportional to their depth in their splay tree. The cost of this traversal can be charged to the splay operations.

Theorem 7. (Multi-Splay Access Lemma)

Let P be any initial reference tree with root r , f be any multiplier greater than 2, and $w(x)$ be any positive weight assignment satisfying the following two conditions:

$$w(v) \geq \max_{u \in \text{descendants}(v,P)} w(u) \qquad f * w(v) \geq \max_{p \in \text{paths}(v,P)} \sum_{u \in p} w(u).$$

Then the running time to access the sequence $\sigma = \sigma_1, \dots, \sigma_m$ is amortized

$$O\left(\sum_{i=1}^m \log(w(r)/w(\hat{\sigma}_i)) + (\log f) * (IB(P, \sigma) + m)\right).$$

The proof for this theorem is similar to the proofs of the preceding theorems. With this theorem, one can prove $O(\log \log n)$ -competitiveness by choosing a balanced reference tree P , setting the weight of every node v to 1, and choosing f to be $O(\log n)$. One can also prove the $O(\log n)$ amortized bound by choosing a balanced reference tree P , setting the weight of node v to be $\frac{1}{2^{\text{refDepth}(v)}}$, and choosing f to be $O(1)$. Unfortunately, the two constraints above prevent the use of the Multi-Splay Access Lemma for proving the classical splay tree properties.

5 Sequential Access Takes Linear Time

We begin with several simple lemmas (that are proved in the appendix).

Lemma 1. *The cost of a switch is $O(\log n)$ worst case.*

Lemma 2. *During a sequential access of all nodes of T , when a node with a left child (in P) is accessed, exactly one switch occurs.*

Lemma 3. *In a splay tree T_S with root r (r changes as the root changes), if all splay operations are performed on a connected set of nodes $S \subseteq T_S$, and $r \in S$, then the splay algorithm will never rotate any node outside of S . (This allows us to analyze the cost of splaying assuming all nodes in $(T_S - S)$ do not exist.)*

Lemma 4. *During a sequential access sequence, when accessing nodes from the right ref-subtree R of y , the multi-splay algorithm touches at most 2 nodes outside of R .*

Lemma 5. *In a red-black tree T_{RB} of n nodes, $\sum_{v \in T_{RB}} \lg |\text{subtree}(v)| = O(n)$.*

Theorem 8. *In any multi-splay tree T of n nodes, the cost of the access sequence $\sigma = \sigma_1, \dots, \sigma_n$, where $\hat{\sigma}_i < \sigma_{i+1}$ is $O(n)$.*

Proof of Theorem: In this proof, we assume that P is a balanced BST, such as a red-black tree [GS78], and we assume for simplicity that it is full. Using the previous lemmas, we can develop a recurrence for the cost of sequential access. First, we define $\text{rightParent}(v)$ to be p if the left child of p is v . Also, we define the *right ascending path* of v to be the set of nodes u , such that $\text{rightParent}^*(v) = u$. Finally, we define $A(v)$ to be the size of the right ascending path of v . We analyze the cost of sequentially accessing all the nodes of a multi-splay tree T in terms of the cost of sequentially accessing subtrees of T 's reference tree. More specifically, we recursively account for the cost as follows:

$$\text{Time}(t) = \text{Time}(\text{leftRefSubtree}) + \text{Time}(\text{root}(t)) + \text{Time}(\text{rightRefSubtree}),$$

where t is some subtree of T 's reference tree, and $\text{Time}(t)$ is the amortized time T uses when sequentially accessing the nodes of t (we stress that this is within the context of sequential access to *all* nodes of T , not just the ones in t).

However, to tightly bound the time for accessing the root of t , we need to incorporate $A(\text{root}(t))$. Hence, we define

$$\text{Time}(t, a) = \text{Time to sequentially access all nodes in } t, \text{ for which } A(\text{root}(t)) = a,$$

where t is a subtree of T 's reference tree (taken within the context of T 's full reference tree, so that t 's root may have a non-trivial right ascending path). With this expanded accounting method, the cost of sequentially accessing all of the nodes of T is $\text{Time}(P, 1)$.

In general, we can write

$$\text{Time}(t, a) = \text{Time}(t_L, a + 1) + \text{Time}(t_R, 1) + O(a + \log |t|),$$

for the case in which $\text{root}(t)$ is an internal node because $\text{root}(t_L)$ has a right ascending path with one more node than the path of $\text{root}(t)$, $\text{root}(t_R)$ has a right ascending path including just itself, and accessing $\text{root}(t)$ causes at most one switch by Lemma 2, whose running time is $O(a + 1 + \log |t|)$ worst-case because the number of nodes touched during a switch at node $\text{root}(t)$ is $O(2 + A(\text{root}(t)) + \log |t|) = O(A(\text{root}(t)) + \log |t|)$. The $O(A(\text{root}(t)) + \log |t|)$ bound is true because at most 2 nodes higher in P than $\text{root}(t)$'s right ascending path are touched as seen by Lemma 4, and the number of nodes in $\text{root}(t)$'s splay tree including $\text{root}(t)$'s right ascending path and below is $A(\text{root}(t)) + \text{height}(t)$, which is $O(A(\text{root}(t)) + \log |t|)$.

For the base case in which $\text{root}(t)$ is a leaf in P , we have

$$\text{Time}(t, a) = O(a^2)$$

because at most a switches occur during the access of $\text{root}(t)$ ¹¹, each of which costs $O(a)$ using similar logic to above, for a total of $O(a^2)$.

To see that this recurrence solves to $O(n)$, we show how to account for all of the $O(a + \log |t|)$ terms and all of the $O(a^2)$ terms so that their costs total $O(n)$. For each t such that $\text{root}(t)$ is not a leaf, note that if we spread the $O(a) = O(A(\text{root}(t)))$ portion of the cost evenly among the nodes of $\text{root}(t)$'s right ascending path, each node v in the reference tree is charged at most $O(\text{height}(v)) = O(\log |\text{subtree}(v)|)$. Similarly, to account for the $O(a^2)$ cost for each leaf l , we charge $\Theta(k + 1)$ to $\text{rightParent}^k(l)$ so that each node is charged at most $O(\text{height}(v)) = O(\log |\text{subtree}(v)|)$. Thus, it suffices to show that $\sum_{v \in P} O(\log |\text{subtree}(v)|) = O(n)$, which is true by Lemma 5 (here we assume that the reference tree is a red-black tree). □

6 Making the Data Structure Dynamic

By modifying our data structure slightly, we can support insert and delete while maintaining all of the properties of Section 4, including $O(\log \log n)$ -competitiveness. To think about what is necessary for supporting insert and delete, it is illustrative to think about the effect of insert and delete on the reference tree. When nodes are inserted into and deleted from the reference tree we need to maintain the invariants that every internal node has exactly one preferred child, and that the tree is balanced. We meet the single preferred child requirement by making a constant number of switches prior to each rotation. We meet the balance requirement by allowing rotations on the reference tree P (after insertion and deletion), and making P a dynamic red-black tree. Because the reference tree is implicitly maintained, we need to be able to simulate the update operations over the reference tree (e.g., rotations, pointer traversals) efficiently. Simulating each such operation turns out to cost $O(\log \log n)$ amortized time in an MST, so it is important that the corresponding reference tree requires only $O(m)$ virtual traversals and virtual rotations during a sequence of m operations (finding the *location* of the update does *not* involve virtual traversals). Red-black trees meet this requirement because they require only $O(1)$ amortized time to rebalance after an insert or delete [Tar83].

6.1 Defining Competitive Analysis in a Dynamic BST

Before we can argue about the competitiveness of dynamic multi-splay trees, we must introduce an intuitive definition of what it means for a dynamic BST to be competitive. We assume an arbitrary dynamic BST algorithm A must execute a sequence of operations $\sigma = \sigma_1, \dots, \sigma_m$, each of which is $\text{query}(\hat{\sigma}_i)$, $\text{insert}(\hat{\sigma}_i)$, or $\text{delete}(\hat{\sigma}_i)$.

For each σ_i , we assume A must pay the following costs:

- To execute $\text{query}(\hat{\sigma}_i)$, it must pay for traversing each edge from the root to $\hat{\sigma}_i$.
- To execute $\text{insert}(\hat{\sigma}_i)$, it must insert the node at a leaf and must pay for the traversal to get there. This is reasonable because A must search for $\hat{\sigma}_i$ to realize its BST does not contain it.

¹¹Because the deepest left ancestor v of $\text{root}(t)$ was just queried, there is always a preferred path from the root of P to v , and the number of nodes between v and $\text{root}(t)$ is at most a .

- To execute $delete(\hat{\sigma}_i)$, similarly, it must pay for accessing $\hat{\sigma}_i$, for performing rotations until $\hat{\sigma}_i$ has no children, and then pay a constant cost for removing it.¹²

During (or after) each operation, a BST algorithm may perform any rotations it wishes at a cost of one per rotation. The cost of an operation is simply the total number of nodes touched, plus the number of rotations. Without insert and delete, this definition would be identical to the one in Section 1.1. From this point onward, we use $OPT(\sigma)$ to refer to the cost of optimal dynamic BST algorithm serving σ .

6.2 Dynamic Interleave Lower Bound

With our new definitions, we must prove a new lower bound for $OPT(\sigma)$. Fortunately, techniques similar to those in [Wil89] suffice. Our new lower bound is an extension of the one in [DHIP04], which is a variant of Wilber’s first lower bound. For completeness, we include the proof in our appendix.

As in the original definition of the interleave bound, for each node v in the initial reference tree P_0 , we track if the last query in $refSubtree(v)$ is in either $L^v = leftRefSubtree(v) \cup \{v\}$ or $R^v = rightRefSubtree(v)$. Whenever the tracking for a node changes, we increment the dynamic interleave bound, $DIB(\rho, \sigma)$, by one. For an insert of v , we treat it as if both $predecessor(v)$ and $successor(v)$ were queried (because both of these nodes must be touched to insert v at a leaf). For a delete of v , we treat it as if $predecessor(v)$, v , and $successor(v)$ were queried because all three of these nodes must be touched in order to rotate v to a leaf of the BST. Whenever we rotate a node v , we reset the tracking of v and $refParent(v)$ to L^v but do not increase the interleave bound. Without insertions, deletions, and rotations, this definition would be identical to the one of the original interleave bound.

Theorem 9. (*Dynamic Interleave Bound*) For a sequence of operations $\sigma = \sigma_1, \dots, \sigma_m$ where each σ_i is a query, insert, or delete, the cost of an arbitrary BST algorithm A on σ is $\Omega(DIB(\rho, \sigma)/2 - n - 2k + m)$, where n is the number of nodes in P_m , $\rho = \rho_1, \dots, \rho_m$ is a sequence of changes to P , where each ρ_i contains a sequence of rotation operations to be performed on P (insertions and deletions in P correspond to those in σ), and k is the number of rotate operations in ρ (i.e., $k = \sum_{i=1}^m \#$ of rotations in ρ_i).¹³

Remark. Note that as in [Tar83], deletion of node v in the reference tree is accomplished by “splicing out” v unless it has two non-null children, in which case v is swapped with its predecessor and then spliced out.¹⁴

The operations ρ_i are the changes to P that occur between successive operations of σ (for MSTs ρ_i represents the rebalancing rotations performed on its reference tree following an insert or a delete). Different ρ sequences give different lower bounds on the cost of σ .

Proof: Shown in appendix.

6.3 Simulating Reference Tree Traversals and Rotations

To simulate a reference tree pointer traversal from node v in an MST, we need only to search for the relevant parent or child node, which can be accomplished if we add 3 new fields to store the values of the parent and children of each node in the reference tree. The cost of this search can be paid for by performing a constant number of switches (notice that the path from v to v ’s child or parent in the reference tree spans at most two splay trees), for a total amortized cost of $O(\log \log n)$. Essentially, each path we traverse in the MST will be splayed, which ensures the amortized cost bound. We omit the details for brevity.

To simulate a right rotation on a node v in its (implicit) reference tree, a multi-splay tree first ensures that v ’s preferred child is its right child, and v ’s parent’s preferred child is its left by performing either 1 or 2 switches on v and v ’s parent. By meeting these requirements T ensures that if its reference tree satisfies the preferred path property before the rotation, it will still satisfy that property after the rotation, as seen in Figure 2.

¹²In this model, we do not allow BSTs to swap nodes and contract edges during deletion. As a result, this model is slightly more restrictive.

¹³As a detail, the lower bound tree is only permitted to swap a node v with $successor(v)$ higher up in P (as for a deletion) when v ’s reference subtree (excluding v) is isolated in a single subtree of T , so as to ensure that no transition points change (the nodes in v ’s left ascending path in the reference tree lose a member of their right subtree), except for the (at most one) node for which v is the transition point. Note that MSTs satisfy this requirement when they perform swaps (See Figure 4).

¹⁴Although our model for BST deletion does not allow such swapping/splicing, MSTs will only be *simulating* them while adhering to our dynamic BST model.

Figure 2: A rotation on v in the reference tree. For a right (left) rotation, we must make sure v 's preferred child is right (left), and p 's preferred child is v .

Figure 3: Observe that after we call $switch(v)$ and $switch(p)$, the sets of nodes in L_v and R_p form two subtrees in an MST. A rotation of v over p in the reference tree decreases the depth value of each of the nodes in L_v by one, and increases the depth value of each of the nodes in R_p by one (Shown in Figure 2). Because L_v and R_p are grouped together by the switches, the updates in depth values cost $O(1)$ after performing the switches.

In order to perform switches efficiently, T also needs to update the fields in each of its nodes v when its reference tree changes. Recall that we store $refDepth$ (the depth of v in the reference tree) and $minDepth$ (the minimum $refDepth$ of all the nodes in v 's splay subtree). To update these values efficiently, we do not store the values explicitly. Instead, in v we store $refDepth(v) - refDepth(parent(v))$ and $minDepth(v) - minDepth(parent(v))$ (the parent of the root has a $refDepth$ and $minDepth$ equal to 0). This is analogous to the technique used in link-cut trees [ST85].

Let v be the node we rotate in the reference tree P (and the corresponding node in the MST T). Let p be the parent of v in P . Without loss of generality, we assume v is the left child of p . At first glance, a rotation of v over p in P changes the $refDepth$ value for many nodes, so it would be difficult to update. However, the sets of nodes whose depths change constitute two subtrees in the reference tree. More specifically, the $refDepth$ of each node in $leftRefSubtree(v)$, L_v , decreases by one, while the $refDepth$ of each node in $rightRefSubtree(p)$, R_p , increases by one. Using this observation, we can decrease the depth value of all of the nodes in v 's ref-subtree by executing $switch(v)$ and $switch(p)$ in T , which isolates L_v and R_p as shown in Figure 3 so we can change the difference value at a single node to decrease (or increase) the stored $refDepth$ of each node in L_v (or R_p) by one. This method can be used for the $minDepth$ field as well. Any changes to red-black tree fields are locally contained, so this technique is unnecessary for such fields.

Hence, a rotation in P can be simulated in T using a constant number of switches and field updates, so its amortized cost is $O(\log \log n)$ if the reference tree is balanced.

6.4 Implementing Insertion and Deletion

To insert $\hat{\sigma}_i$, we perform a normal BST insert, access the inserted node, and then rebalance the reference tree using amortized $O(1)$ simulated rotations and pointer traversals. We also insert it into the virtual reference tree by finding its $refParent$ on the way down the access path, its $refParent$ is the node of maximum $refDepth$ on the access path.

For deletion, we consider the case in which $\hat{\sigma}_i$ has two children in the reference tree (the other two cases are simpler). Before rebalancing the reference tree using amortized $O(1)$ simulated rotations and pointer traversals, we must first swap $\hat{\sigma}_i$ with $predecessor(\hat{\sigma}_i)$ and splice out $\hat{\sigma}_i$ using a constant number of switches, rotations, and field updates in addition to a constant number of accesses to $predecessor(\hat{\sigma}_i)$, $\hat{\sigma}_i$, and $successor(\hat{\sigma}_i)$, which will be justified in Section 6.5. To accomplish this, we first perform the sequence: $query(predecessor(\hat{\sigma}_i))$, $switch(refParent(predecessor(\hat{\sigma}_i)))$, $query(predecessor(\hat{\sigma}_i))$, $query(successor(\hat{\sigma}_i))$, and $query(\hat{\sigma}_i)$. Notice that this sequence adheres to our cost specification, and results in an MST that looks like the one in Figure 4.

There are two important aspects of this MST. First, $predecessor(\hat{\sigma}_i)$, $\hat{\sigma}_i$, and $successor(\hat{\sigma}_i)$ are located close together, so that $O(1)$ rotations suffices to make $\hat{\sigma}_i$ a leaf so that it can be deleted. Second, $predecessor(\hat{\sigma}_i)$'s

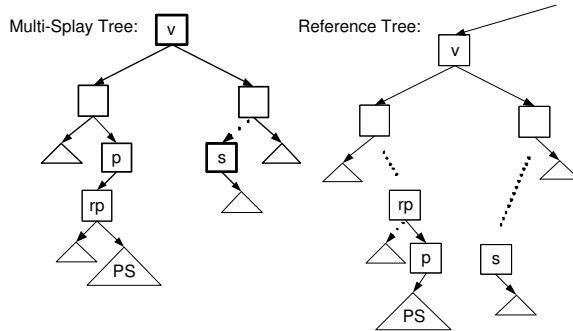

Figure 4: An example of what an MST looks like during deletion of node $\hat{\sigma}_i$, with $v = \hat{\sigma}_i$, $p = \text{predecessor}(\hat{\sigma}_i)$, $s = \text{successor}(\hat{\sigma}_i)$, $rp = \text{refParent}(\text{predecessor}(\hat{\sigma}_i))$ after the sequence $\text{query}(p)$, $\text{switch}(rp)$, $\text{query}(p)$, $\text{query}(s)$, and $\text{query}(v)$.

subtree is isolated in its own subtree of the MST (the subtree PS in Figure 4), so that we can decrement all of its nodes' refDepth and minDepth fields in $O(1)$ time just by changing the fields in the root of PS . We omit most of the details, but remark that once $\hat{\sigma}_i$ is rotated to a leaf and deleted, the depth values of PS are adjusted, and $\text{predecessor}(\hat{\sigma}_i)$ has its fields set so that it takes $\hat{\sigma}_i$'s place in the reference tree, we need only to recompute the minDepth fields of the ancestors of $\text{predecessor}(\hat{\sigma}_i)$ and reset the parent and child value fields (used to during virtual pointer traversals as mentioned in Section 6.3) of the nodes whose parents or children change in the reference tree (i.e., the parents and children of $\hat{\sigma}_i$ and $\text{predecessor}(\hat{\sigma}_i)$ in the reference tree), requiring only a constant number of field updates and reference pointer traversals, each costing $O(\log \log n)$.

6.5 Proof of Running Time Bounds

Without insert and delete, the analysis in Section 4 applies. For the insert and delete operations, only $O(1)$ amortized reference tree rotations are required to rebalance the tree, so that the total amortized cost is $O(\log \log n)$, which does not affect the $O(\log \log n)$ -competitiveness of the operations or the $O(\log n)$ amortized cost of them. For insert, our model requires us to pay for traversing the path to a leaf, so the cost is accounted for as in Section 4.

For delete operations, the additional cost of querying $\text{predecessor}(\hat{\sigma}_i)$, $\hat{\sigma}_i$, and $\text{successor}(\hat{\sigma}_i)$ is accounted for by the fact that any deletion algorithm adhering to our model must touch these three nodes to rotate $\hat{\sigma}_i$ to a leaf. Note that the order of these touches (and number of them, if the number is $O(1)$) only affects the number of switches by a constant factor, so such variations do not affect the $O(\log \log n)$ -competitiveness of MSTs. Also, the additional bookkeeping work and actual deletion of $\hat{\sigma}_i$ requires only $O(\log \log n)$ amortized time as argued in Section 6.4.

Because the strongest assumption made in Sections 4 and 5 was that the reference tree was a red-black tree, and because the dynamic interleave bound is only weaker than the original interleave bound by $O(m)$, all of the proofs in Sections 4 and 5 still apply.

7 Conclusions and Future Work

In this paper we showed that multi-splay trees achieve $O(\log \log n)$ -competitiveness, $O(\log n)$ amortized time per query, and $O(\log^2 n)$ worst-case query time. We then combined these proofs to show the access lemma for multi-splay trees – a parameterizable theorem for analyzing multi-splay tree query sequences. We also proved that sequential access in multi-splay trees takes only linear time.

We also considered allowing insertions and deletions, in addition to queries. We extended the interleave lower bound to this case, and showed how to carry out these operations in multi-splay trees. We proved that the same bounds quoted above for the query-only case apply when insertions and deletions are also allowed if we use a red-black tree with bottom-up $O(1)$ rebalancing for the reference tree.

The multi-splay algorithm is similar to splaying, but differs in a few important ways. Consider modifying the algorithm so that it does not splay z_i . In this modified algorithm, an access to a node v is then a series of partial splays (ones that stop before getting all the way to the root) of nodes on v 's path to the root. The pattern is that starting at an ancestor of v , we splay for a while, stop, then move to an ancestor, then splay for a while, then stop, then move to an ancestor, etc. Finally we switch v so that it moves to the root. These partial splays keep the

multi-splay tree somewhat balanced (i.e., keep the maximum depth bounded by $O(\log^2 n)$). Moreover, one way of thinking about the marking of root bits is that it effectively “removes” from the tree a large amount of weight. This allows us to prove tighter bounds on the running time than can be proven for splay trees.

Given the similarities between multi-splay trees and classical splay trees, it is natural to ask whether splay trees are also $O(\log \log n)$ -competitive. It is also natural to ask whether multi-splay trees share some of the other nice properties of splay trees, such as static optimality.

As far as we know, multi-splay trees may be dynamically optimal. Is this true? One big difficulty in addressing this problem is the lack of tight lower bounds on the cost of accessing a sequence. The static interleave bound is insufficient, because it is known to be off by a factor of $\log \log n$ for some sequences.

A Notation

- $A(v)$ = the size of the *right ascending path* of v
- *dashed edge* = the edges that connect different splay trees
- $\text{descendants}(v, P)$ = all the descendants of v in tree P
- DIB = new dynamic interleave bound
- DIB_i = the number of switches that must be made in P_i (which is implicit from ρ)
- refDepth = the depth of a node in the reference tree (root has depth 1)
- IB = static interleave bound
- $\text{leftRefSubtree}(v)$ = the left subtree of v in the reference tree
- $L_i^y = \text{leftRefSubtree}(v) \cup \{y\}$ during the execution of σ_i
- $\text{OPT}(\sigma)$ = minimum cost of a BST to serve the sequence σ
- P = a reference tree
- P_i = the state of P after σ_i is executed
- $\text{paths}(v, P)$ = the set of all paths from node v in tree P to a descendant of v with no children
- *preferred child* = the child that is more recently touched if we were to perform all the operations on reference tree
- *preferred path* = a path formed by the preferred child relation in the reference tree. Specifically, if a node v is in a preferred path, then v 's preferred child is also in the preferred path.
- minDepth of a node v in an MST = the minimum refDepth of all the nodes in v 's splay subtree
- ρ = a sequences of changes to the reference tree P
- ρ_i = the i^{th} change to the reference tree P
- $r_i = \text{root}(t_i)$ = the root of the i^{th} splay tree
- $R_i^y = \text{rightRefSubtree}(y)$ during the execution of σ_i
- refDepth of a node v in an MST = the depth of node v in the reference tree
- $\text{refSubtree}(v)$ = the subtree rooted at v in the reference tree (this tree is the same regardless of the preferred child)
- *right ascending path* of v = the set of nodes u , such that $\text{rightParent}^*(v) = u$
- rightParent of a node $v = p$ if p 's left child is v .
- $\text{rightRefSubtree}(v) = \text{right refSubtree}(v)$ = the right subtree of v in the reference tree
- $\text{root}(t)$ = the root of tree/subtree t (either a splay tree, an MST, or a reference tree)
- σ = the sequence of queries (later we generalize to support insert and delete.)
- σ_i = the i^{th} operation
- $\hat{\sigma}_i$ = the key or node of σ_i
- *solid edge* = the edges inside a single splay tree
- $s(v)$ = size of $v = \sum_{u \in \text{splaySubtree}(v)} w(u)$
- $\text{splaySubtree}(v)$ = the subtree rooted at v in multi-splay tree restricted to v 's splay tree
- $\text{subtree} = \text{refSubtree}$
- *sucessor* of key v in splay tree t = the key of the smallest node larger than v in t .
- T = multi-splay tree
- $|t|$ = the number of nodes in $\text{subtree}(t)$, including $\text{root}(t)$
- t_i = the splay tree involved in i^{th} switch during an operation
- T_i = the state of T when σ_i is executed

- t_L = the left subtree of tree t
- t_R = the right subtree of tree t
- T_{RB} = a red black tree
- T_S = a splay tree
- y = the node that the multi-splay algorithm switches in T
- y_i = the i^{th} node switched during an operation
- $w(v)$ = weight of v
- x_i, z_i = the two additional nodes we splay during the i^{th} switch

B Proof of Lemmas for Sequential Access

Lemma 1. *The cost of a switch is $O(\log n)$ worst case, not amortized.*

Proof: Each switch consists of 3 splays and up to 2 root markings/unmarkings. Because the size of each splay tree is $O(\text{height}(P)) = O(\log n)$, the worst case cost of the splays is $O(\log n)$, and clearly the root markings cost $O(1)$ worst case. \square

Lemma 2. *During a sequential access of all nodes of T , when a node with a left child (in P) is accessed, exactly one switch occurs.*

Proof: Within a sequential access, a query to a node v with a left child immediately follows a query to a node in its left ref-subtree, so the preferred path from the root includes v . The one switch occurs because the multi-splay algorithm always switches the node that is accessed. \square

Lemma 3. *In a splay tree T_S with root r (r changes as the root changes), if all splay operations are performed on a connected set of nodes $S \subseteq T_S$, and $r \in S$, then the splay algorithm will never rotate any node outside of S . (This allows us to analyze the cost of splaying assuming all nodes in $(T_S - S)$ do not exist.)*

Proof: Observe that if all the rotations are performed on nodes in S , then the set of nodes S will always be a connected set of nodes that includes the root of T_S . A splay operation on $v \in S$ will rotate nodes on the path from v to the root. Because S consists of a connected set of nodes, all of these rotated nodes must be in S . Thus, the invariant that S is a connected set and $r \in S$ is maintained. \square

Lemma 4. *During a sequential access sequence, when accessing nodes from the right ref-subtree R of y , the multi-splay algorithm touches at most 2 nodes outside of R .*

Proof: After y is accessed, y becomes the root of the MST, its right child x is the successor of R , and all the nodes of R are in x 's left splay subtree (See Figure 1). The following splays induced by querying R can only touch y , R , and x by lemma 3. \square

Lemma 5. *In a red-black tree T_{RB} of n nodes, $\sum_{v \in T_{RB}} \lg |\text{subtree}(v)| = O(n)$.*

Proof: Suppose we merge all the red nodes with their parents. For instance, if a black node originally has two red children and each red child has two black children, then we are left with a black node with 4 black children after the merge. (Essentially, we are converting the red-black tree into its corresponding 2-3-4 tree.)

Since every root-to-leaf path in a red black tree has the same number of black nodes, each black node can have at most two red children, and each red node has two black children, the merge process reduces the number of nodes in the subtree of every black node by at most a factor of 3.

Define $\text{blackHeight}(v)$ to be the number of black nodes from v to leaf, excluding v . Observe that the number of black nodes at $\text{blackHeight}(v)$ is at most $\frac{n}{2^{\text{blackHeight}(v)}}$. Also, note that the number of nodes in a black node v 's subtree is at most $4^{\text{blackHeight}(v)}$.

Hence,

$$\begin{aligned}
\sum_{v \in T_{RB}} \lg |\text{subtree}(v)| &\leq 3 * \sum_{v \in T_{RB} \text{ s.t. } v \text{ is black}} \lg |\text{subtree}(v)| \\
&\leq 3 * \sum_{v \in T_{RB} \text{ s.t. } v \text{ is black}} \lg 4^{\text{blackHeight}(v)} \\
&\leq 6 * \sum_{v \in T_{RB} \text{ s.t. } v \text{ is black}} \text{blackHeight}(v) \\
&\leq 6 * \sum_{\text{blackHeight}=0}^{\lceil \lg n \rceil} \text{blackHeight} * \frac{n}{2^{\text{blackHeight}}} \\
&\leq 18n.
\end{aligned}$$

□

C Proof of Multi-Splay Tree Access Lemma

Let P be any initial reference tree with root r , f be any multiplier greater than 2, and $w(x)$ be any positive weight assignment satisfying these two conditions:

$$\begin{aligned}
w(v) &\geq \max_{u \in \text{descendants}(v, P)} w(u) \\
f * w(v) &\geq \max_{p \in \text{paths}(v, P)} \sum_{u \in p} w(u).
\end{aligned}$$

Then the running time to access the sequence $\sigma = \sigma_1, \dots, \sigma_m$ is amortized

$$O\left(\sum_{i=1}^m \log(w(r)/w(\hat{\sigma}_i)) + (\log f) * (IB(P, \sigma) + m)\right).$$

Intuitively, the first weight condition forces the shallower nodes in P to have bigger weight. This is necessary because multi-splay trees tend to access the nodes with lower depth more frequently than the nodes with higher depth in P . As for the second weight condition, it forces P to be somewhat balanced to achieve a reasonable upper bound. As for the multiplier f , it significantly relaxes the second constraint on the growth of $w(x)$.

In the proof, we first bound the time for each switch. Then we bound the time for each access as a function of the number of switches. Then we relate the number of switches to the interleave bound.

Proof: Let the set of keys be $S = a_1, a_2, \dots, a_n$. For any access σ_m , let $\sigma' = \sigma_1, \sigma_2, \dots, \sigma_{m-1}$ be the access sequence before σ_m , and $\sigma = \sigma_1, \sigma_2, \dots, \sigma_m$. Let the k switches made by accessing σ_m be $Y = y_1, y_2, \dots, y_k$, and r_i be the root of the splay tree containing y_i before the access. Define r_0 to be the root of the splay tree containing σ_m .

For a particular switch y_i , we define $s(v)$ to be the size of v before the changes in *isRoot* bit. Similarly, define $s'(v)$ be the size of v after the changes in *isRoot* bit. Each switch operation consists of at most 3 splays (on z_i, y_i, x_i), setting the *isRoot* bit of $\text{child}(z)$, and clearing the *isRoot* bit of $\text{child}(x)$. As a result, the root changes affect the potential of nodes z_i, y_i, x_i . Specifically, $s(z_i)$ decreases by $s(\text{child}(z_i))$; $s(y_i)$ changes by $s(\text{child}(x)) - s(\text{child}(z))$; and x increases by $s(\text{child}(x))$. In addition, from the second condition on the weight assignment, $f * w(y) \geq s(cx)$,

Figure 5: The relationship of $x = x_i$, y_i , $z = z_i$, $cx = \text{child}(x_i)$ and $cz = \text{child}(z_i)$ in both multi-splay tree T (left) and reference tree P (right). This is right after the 3 splays, but before setting the *isRoot* bit for *child*(z) and clearing the *isRoot* bit for *child*(x). It is important to observe that $s(\text{child}(x))$ corresponds exactly to the sum of the nodes on a path in $p(y, P)$

$$\begin{aligned}
\Delta\Phi &= (\lg(s'(x)) - \lg(s(x))) + (\lg(s'(y)) - \lg(s(y_i))) + (\lg(s'(z)) - \lg(s(z))) \\
&\leq \lg(s'(x)/s(x)) + \lg(s'(y_i)/s(y_i)) \\
&\leq \lg((s(x) + s(\text{child}(x)))/s(x)) + \lg((s(y_i) + s(\text{child}(x)))/s(y_i)) \\
&\leq \lg(1 + s(\text{child}(x))/w(y_i)) + \lg(1 + s(\text{child}(x))/w(y_i)) \\
&\leq 2\lg(1 + f) \\
&= O(\lg f).
\end{aligned}$$

Because both x and z are ancestors of y in P , $w(x) \geq w(y)$ and $w(z) \geq w(y)$ by the first condition,

$$\begin{aligned}
\text{Time}(\text{switch}(y_i)) &= \text{Time}(\text{splay}(y_i)) + \text{Time}(\text{splay}(x)) + \text{Time}(\text{splay}(z)) + \Delta\Phi \\
&< O(\lg s(r_i)/s(y_i)) + O(\lg s(r_i)/s(x_i)) + O(\lg s(r_i)/s(z_i)) + O(\lg f) \\
&\leq O(\lg s(r_i)/w(y_i)) + O(\lg s(r_i)/w(x_i)) + O(\lg s(r_i)/w(z_i)) + O(\lg f) \\
&\leq O(\lg s(r_i)/w(y_i)) + O(\lg s(r_i)/w(y_i)) + O(\lg s(r_i)/w(y_i)) + O(\lg f) \\
&= O(\lg s(r_i)/w(y_i)) + O(\lg f) \\
&\leq O(\lg s(r_i)/(s(r_{i-1})/f)) + O(\lg f) \\
&= O(\lg s(r_i)/s(r_{i-1})) + O(\lg f).
\end{aligned}$$

When we access a node in a multi-splay tree, we are just making a series of switches and then doing a final switch. Therefore,

$$\begin{aligned}
\text{Time}(\text{Access}(\sigma_m)) &= \sum_{i=1}^k (\text{switch}(y_k)) + \text{Time}(\text{switch}(\sigma_m)) \\
&= \sum_{i=1}^k O(\lg s(r_i)/s(r_{i-1})) + \sum_{i=1}^k O(\lg f) + O(\lg(s(t)/s(\sigma_m))) \\
&= O(\lg(s(r_k)/s(r_1))) + O(k * (\lg f)) + O(\lg(f * w(r)/w(\sigma_m))) \\
&= O(\lg(w(r)/w(\sigma_m))) + O((k + 1) * (\lg f)).
\end{aligned}$$

Because a switch occurs when the preferred child changes from left to right (or right to left), this is exactly when the previous access in y_i 's subtree in P is in the left subtree (or right subtree) of y , while σ_m is in the right

subtree (or left subtree) of y .¹⁵ Thus, $\forall_{0 < i \leq k} (\mathbf{IB}(T_0, \sigma', y_i) + 1 = \mathbf{IB}(T_0, \sigma, y_i))$. In addition, for all other nodes $v \neq y_i$, the $\mathbf{IB}(T_0, \sigma', v) = \mathbf{IB}(T_0, \sigma, v)$. Hence,

$$k = \mathbf{IB}(T_0, \sigma) - \mathbf{IB}(T_0, \sigma').$$

Thus, exactly $\mathbf{IB}(P, \sigma)$ switches are made for an m element access sequence σ . The amortized running time for the access sequence σ is:

$$\begin{aligned} \text{Time}(\text{Access}(\sigma)) &= \sum_{i=1}^m \text{Time}(\text{Access}(\sigma_i)) \\ &= \sum_{i=1}^m O(\lg(w(r)/w(\sigma_i))) + \\ &\quad \sum_{i=1}^m O((1 + \mathbf{IB}(P, \sigma_1 \dots \sigma_i) - \mathbf{IB}(P, \sigma_1 \dots \sigma_{i-1})) * (\lg f)) \\ &= \sum_{i=1}^m O(\lg(w(r)/w(\sigma_i))) + O((\mathbf{IB}(P, \sigma) + m) * (\lg f)) \\ &= O\left(\sum_{i=1}^m \lg(w(r)/w(\sigma_i)) + (\lg f) * (\mathbf{IB}(P, \sigma) + m)\right). \end{aligned}$$

□

D Proof of the Dynamic Interleave Bound

Here we present an extended version of Wilber's first lower bound [Wil89]. Our presentation is similar to Demaine *et al.*'s, with modifications to permit the lower bound tree to be dynamic.

In our description of the bound, there are two trees, P and T , which are both dynamic BSTs over the same keys. The tree P is a *reference tree* that the lower bound will use (P does not really exist), and each internal node always has exactly one preferred child (as in the reference tree for an MST). The tree T refers to the tree maintained by an arbitrary BST algorithm A adhering to the model described in Section 6.1.

Let $\sigma = \sigma_1, \dots, \sigma_m$ be a sequence of operations on T for which each σ_i is either a query, an insert, or a delete (A is responsible for executing these operations in order).

Because both P and T are dynamic, we often refer to them by their time index. By P_i and T_i , we mean the state of P and T when σ_i is executed. For notational simplicity, P is assumed to be empty initially so P_0 is the empty tree.

Further, because P is dynamic, we need a way to describe changes to it. Let $\rho = \rho_1, \dots, \rho_m$ be a sequence of changes to P , where each ρ_i contains a *sequence* of rotations to be performed on P . Insertions and deletions in the reference tree correspond to the operations in σ and follow the standard BST insert and delete rules (an insertion occurs at the relevant leaf, and a deletion typically swaps the node v to be deleted with *predecessor*(v) and splices out v). The change in ρ_i is performed immediately before σ_i is executed by A (i.e., after σ_{i-1} is executed for $i > 1$). For example, ρ_1 positions all elements that are initially in the BST via a sequence of rotations starting from some BST containing the nodes of T . Whenever a node in P is involved in a rotation (i.e., it is either v or p for a rotation of v over p), its preferred child is set to its leftmost child, if it has a child. This child setting is *not* considered a switch for accounting purposes (e.g., in $\text{DIB}(\rho, \sigma)$ as described below).

If σ_i queries $\hat{\sigma}_i$, P_i *switches* its nodes' preferred children as necessary so as to create a path consisting only of preferred child edges to $\hat{\sigma}_i$ starting from the root. In the case of insert, the switches connect both the predecessor and successor of $\hat{\sigma}_i$ to the root. For delete, *predecessor*($\hat{\sigma}_i$), *successor*($\hat{\sigma}_i$), and $\hat{\sigma}_i$ are connected to the root (note that the order only affects the lower bound by a constant factor). Let $\text{DIB}_i(\rho, \sigma, v)$ be the number of such switches

¹⁵Here we are ignoring the effect of the final switch on the accessed node, which clearly only adds $O(1)$ per access to the total number of switches.

of node v 's preferred child that must be made in P_i (which is implicit from ρ) to accommodate σ_i , and 0 otherwise. Let $\text{DIB}(\rho, \sigma, v) = \sum_{i=1}^m \text{DIB}_i(\rho, \sigma, v)$, and let $\text{DIB}(\rho, \sigma) = \sum_{v \in V} \text{DIB}(\rho, \sigma, v)$, where V is the set of all nodes that are inserted into P at some point.

Our lower-bound proof runs parallel to the proof for a static reference tree in [DHIP04], with some changes to allow P to be dynamic. We define $L^y = \text{leftRefSubtree}(y) \cup y$ and $R^y = \text{rightRefSubtree}(y)$ (L^y and R^y can be indexed by time as well). For a switched node y , define the *transition point* of y to be the highest node z in T such that the path from z to the root contains at least one node from both L^y and R^y . Observe that z is either the lowest common ancestor of L^y or R^y .

We restate a few useful lemmas from [DHIP04] (Lemma 7 is modified to account for P 's being dynamic). The proofs of Lemmas 6 and 8 are the same as in [DHIP04] because these lemmas refer to a snapshot of P .

Lemma 6. [DHIP04] *The transition point z in T_i for a node y in P_i is unique.*

Lemma 7. *Suppose a BST access algorithm does not touch a node z in T for the time interval $i \in [j, k]$, and z is the transition point in T_j for a node y in P_j . Further, suppose that y is not rotated in the reference tree by the execution of $\rho_{j+1}, \dots, \rho_k$ (i.e., there is no rotation in $\rho_{j+1}, \dots, \rho_k$ of v over its parent p where $y = v$ or $y = p$). It follows that z remains the transition point of y for the entire time interval $[j, k]$.*

Proof: Suppose, without loss of generality, that $z \in R_j^y$. Notice that all of R_j^y is in the subtree rooted at z in T_j because z is the lowest common ancestor of R_j^y in T_j . Because z is not touched, z remains the lowest common ancestor of R_i^y for all $i \in [j, k]$. Moreover, at time j the predecessor a of the nodes in the set $\text{subtree}(z) \cap (L_j^y \cup R_j^y)$ is in L^y because $L^y \cup R^y$ forms a contiguous region of keyspace. Notice that a is the deepest left-ancestor of z in T .¹⁶ Thus, no rotation during $[j, k]$ changes the fact that a is the deepest left-ancestor of z , and a cannot be deleted from T during $[j, k]$ because it has a right child. \square

Lemma 8. [DHIP04] *At any time i , no node in T_i is the transition point for multiple nodes in P_i .*

The following theorem relates $\text{DIB}(\rho, \sigma)$ to a lower bound on $\text{OPT}(\sigma)$:

Theorem 9. (Dynamic Interleave Bound) *For a sequence of operations $\sigma = \sigma_1, \dots, \sigma_m$ where each σ_i is a query, insert, or delete, the cost of an arbitrary BST algorithm A on σ is $\Omega(\text{DIB}(\rho, \sigma)/2 - n - 2k + m)$, where n is the number of nodes in P_m , $\rho = \rho_1, \dots, \rho_m$ is a sequence of changes to P , where each ρ_i contains a sequence of rotation operations to be performed on P (insertions and deletions in P correspond to those in σ), and k is the number of rotate operations in ρ (i.e., $k = \sum_{i=1}^m \#$ of rotations in ρ_i).¹⁷*

Proof of Theorem: First, note that the m term in the lower bound appears because each operation costs at least 1.

Following [DHIP04], suppose every time a node y in P is switched from left-to-right the lower bound places a marble on the transition point of y in T . Moreover, whenever the lower bound rotates v over p in P , it removes any marbles from transition point of v and of p in T . On the other hand, whenever A touches a node, it discards all of the marbles at that node, and when A deletes a node it removes the marble from that node's transition point (if it exists). Clearly, if the number of marbles sitting on a node never exceeds 1 then the number of marbles removed is at most A 's cost for σ (if we charge A 2 units for each delete it does).

Because there are n nodes in T_m , the k rotations cause the removal of at most $2k$ marbles, and deletions remove only $O(m)$ marbles, to prove the theorem it suffices to show that no node can ever have more than one marble. This is true because the number of marbles placed is at least half the number of total switches (because there are at least as many left-to-right switches as right-to-left switches) and A must remove all of the marbles that are placed on T except those that either remain on T_m at the end (up to n) or are removed by the lower bound (up to $2k$).

To see that no node can ever have more than one marble, notice that by Lemma 8 no two nodes in P_i ever have the same transition point in T_i . As argued in [DHIP04], when a left-to-right switch is made at y at times i and j ($i < j$), the transition point for y in T_i must be touched at some time during the interval $(i, j]$, assuming that

¹⁶By "deepest left-ancestor of z ", we mean the parent of the highest node in z 's right ascending path.

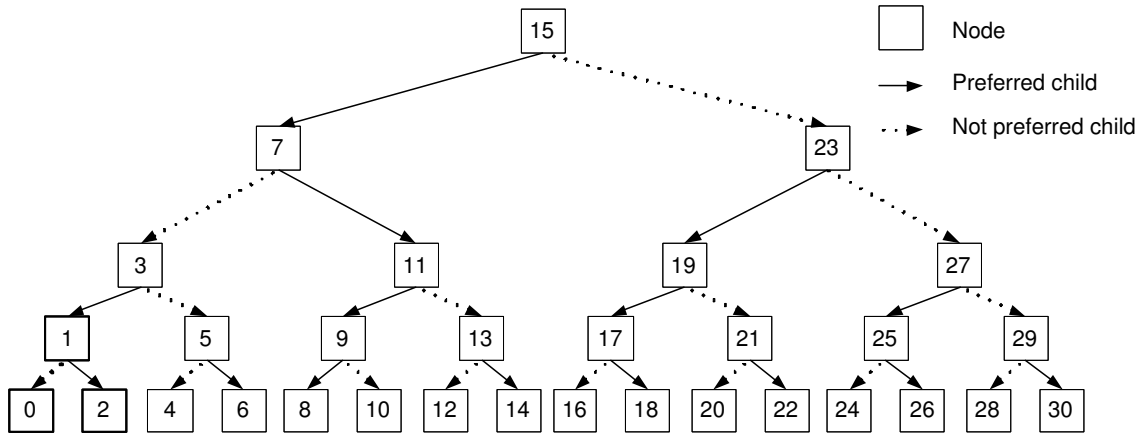

¹⁷As a detail, the lower bound tree is only permitted to swap a node v with $\text{successor}(v)$ higher up in P (as for a deletion) when v 's reference subtree (excluding v) is isolated in a single subtree of T , so as to ensure that no transition points change (the nodes in v 's left ascending path in the reference tree lose a member of their right subtree), except for the (at most one) node for which v is the transition point. Note that MSTs satisfy this requirement when they perform swaps (See Figure 4).

the transition point remains constant during that interval. By Lemma 7, y 's transition point z during this interval remains constant unless z was rotated in T , in which case A removed its marbles, or the lower bound executed a rotation involving y , in which case the lower bound removed the marbles of z . \square

E An Example of an MST and the Corresponding Reference Tree

Figure 6 shows what an MST looks like, and shows the corresponding reference tree that is stored implicitly in the MST.

Representation in P - We use this representation for explanation and proof

A Possible Representation -
16 interconnected splay trees
that form a single BST

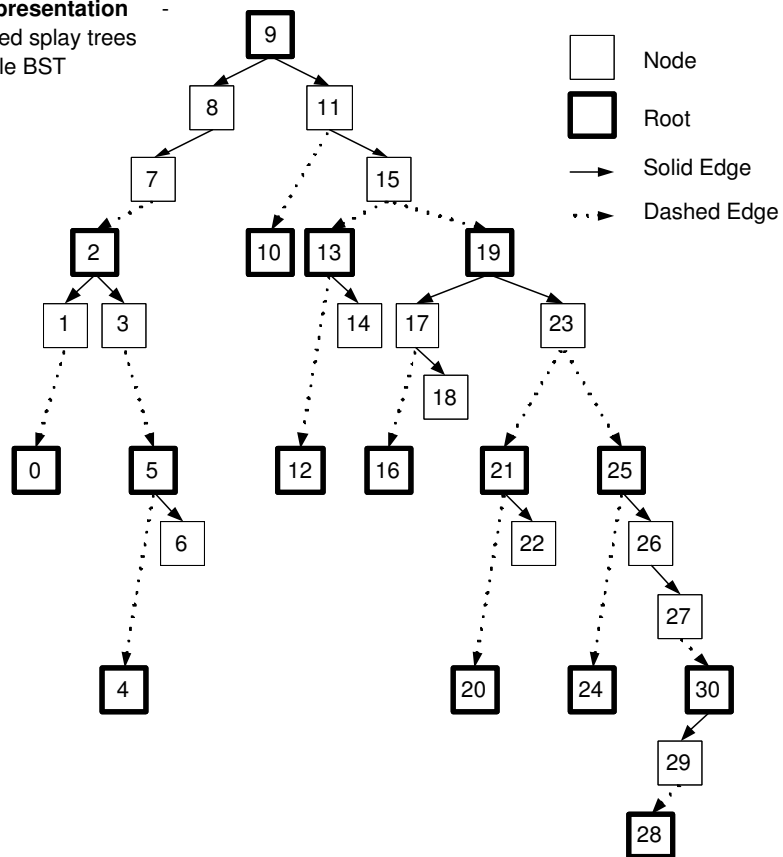

Figure 6: Multi-Splay Data Structure – One can always obtain P from T by a set of rotations on solid edges.
