Abstract

When people observe and interact with physical spaces, they are able to associate functionality to regions in the environment. Our goal is to automate dense functional understanding of large spaces by leveraging sparse activity demonstrations recorded from an ego-centric viewpoint. The method we describe enables functionality estimation in large scenes where people have behaved, as well as novel scenes where no behaviors are observed. Our method learns and predicts “Action Maps”, which encode the ability for a user to perform activities at various locations. With the usage of an egocentric camera to observe human activities, our method scales with the size of the scene without the need for mounting multiple static surveillance cameras and is well-suited to the task of observing activities up-close. We demonstrate that by capturing appearance-based attributes of the environment and associating these attributes with activity demonstrations, our proposed mathematical framework allows for the prediction of Action Maps in new environments. Additionally, we offer a preliminary glance of the applicability of Action Maps by demonstrating a proof-of-concept application in which they are used in concert with activity detections to perform localization.

1. Introduction

The goal of this work is to endow intelligent systems with the ability to understand the functional attributes of their environment. Such functional understanding of spaces is a crucial component of holistic understanding and decision making by any agent, human or robotic. Functional understanding of a scene can range from the immediate environment to the distant. For example, at the scale of a single room, a person can perceive the arrangement of tables, chairs, and computers in an office environment, and reason that they could sit down and type at the computer. People can also reason about the functionality about nearby rooms, for example, the presence of a kitchen down the hall from the office is useful functional and spatial information for when the person decides to prepare a meal. The goal of this work is to learn a computational model of the functionality of large environments, called Action Maps (AMs), by observing human interactions and the visual context of those
action within a large environment.

There has been significant work in the area of automating the functional understanding of an environment, though much has focused on single scenes [9, 4, 11, 10, 2, 5]. In this work, we aim to extend automated functional understanding to very large spaces (e.g., an entire office building or home). This presents two key technical challenges:

- How can we capture observations of activity across large environments?
- How can we generalize functional understanding to handle the inevitable data sparsity of less explored or new areas?

In order to address the first challenge of observing activity across large environments, we take a departure from the fixed surveillance camera paradigm, and propose an approach that uses a first-person point-of-view camera. By virtue of its placement, its view of the wearer’s interactions with the environment is usually unobstructed by the wearer’s body and other elements in the scene. An egocentric camera is portable across multiple rooms, whereas fixed cameras are not. An egocentric camera allows for the observation of hand-based activities, such as typing or opening doors, as well as the observation of some ego-motion based activities, such as sitting down or standing. The first-person paradigm is well suited for large-scale sensing and allows observation of interactions with many environments.

Although we can capture a large number of observations of activity across large environments with wearable cameras, it is still not practical to wait to observe all possible actions in all possible locations. This leads to the second technical challenge of generalizing functional understanding from a sparse set of action observations, which requires generalization to new locations. Our method generalizes by using another source of visual observation – which we call side-information – that encodes per-location cues relevant to activities. In particular, we propose to extract visual side-information using scene classification [22] and object detection [6] techniques. With this information, our method learns to model the relationship between actions, scenes, and objects. In a scene with no actions, we use scene and object information, coupled with actions in a separate scene, to infer possible actions. We propose to solve the problem of generalizing functional understanding (i.e., generating dense AMs) by formulating the problem as matrix completion. Our method constructs a matrix where each row represents a location and each column represents an action type (e.g., read, sit, type, write, open, wash). The goal of matrix completion is to use the observed entries to fill the missing entries. In this work, we make use of Regularized Weighted Non-Negative Matrix Factorization (RWNMF) [7], allowing us to elegantly leverage side-information to model the relationship between activities, scenes, and objects, and predict missing activity affordances.

To the best of our knowledge, this is the first work to generate Action Maps, such as those in Figures 1 and 2, over large spaces using a wearable camera. The first-person vision paradigm is an essential tool for this problem, as it can capture a wide range of visual information across a large environment. Our approach unifies scene functionality information via a regularized matrix completion framework that appropriately addresses the issue of sparse observations and provides a vehicle to leverage visual side information.

We demonstrate the efficacy of our proposed approach on five different multi-room scenes: one home and four office environments. Our experiments in real large-scale environments show how first-person sensing can be used to efficiently observe human activity along with visual side-information across large spaces. 1) We show that our method can be used to model visual information from both single and multiple scenes simultaneously, and makes efficient use of all available activity information. 2) We show that our method’s power increases as the set of performed activity increases. 3) Furthermore, we demonstrate how our proposed matrix factorization framework can be used to leverage sparse observations of human actions along with visual side-information to perform functionality estimation of large novel scenes in which no activities have been demonstrated. We compare our proposed method against natural baselines such as object-detection-based Action Maps and scene classification, and show that our approach outperforms them in nearly all of our experiments. 4) Additionally, as a proof-of-concept application of the rich information in an Action Map, we present an application of our Action Maps as priors for localization.

1.2. Background

Human actions are deeply connected to the scene. Scene context (e.g., a chair or common room) can be a strong in-
indicator of actions (e.g., sitting). Likewise, observing an action like sitting, is a strong indicator that there must be a sittable surface in the scene. In the context of time lapse video, Fouhey et al. [4] used detection of sitting, standing, and walking actions to obtain better estimates of 3D geometry for a single densely explored room. Gupta et al. [9] addressed the inverse problem of inferring actions from estimated 3D scene geometry using a single image of a room. Their approach synthetically inserted skeleton models into the 3D scene to reason about possible functional attributes of the scene. Delaitre et al. [2] also used time lapse video of human actions to learn the functional attributes of objects in a single scene. The work of Savva et al. [16] obtains a dense 3D representation of small workspace (e.g. desk and chair space) and learns the functional attributes of the scene by observing human interactions. Similar to previous work, this work seeks to understand the functionality of scenes. However, limitations of previous work include the reduced size of the physical space and the presumed density of interactions. In contrast, our approach attempts to infer the dense functionality over an entire building (e.g., office floor or house), and reasons about multiple large scenes simultaneously by modeling the relationship between scene information, object information, and sparse activities.

Another flavor of approaches reason in the joint space of activities and objects. In Moore et al. [13], human actions are recognized by using information about objects in the scene. Gall et al. [5] uses human interaction information to perform unsupervised categorization of objects. Other approaches have capitalized on the interplay between actions and objects: Gupta et al. [8] demonstrate an approach to use object information for pose detection, and Yao et al. [20] jointly model objects and poses to perform recognition of both objects and actions. The approach of [14] performs object recognition by observing human activities, and notes an important idea that our approach also uses: whereas object information may sometimes be too small in detail, human activities usually are not. We capitalize on this observation close-up observation capability of an egocentric camera.

The egocentric paradigm is an excellent method for understanding human activities at close range [18, 3, 15, 12]. Our work builds on such egocentric space recognition techniques by associating actions with physical locations in a single holistic framework. By bringing together ideas from single image functional scene understanding, object functionality understanding and egocentric action analysis, we propose a computational model that enables cross-building level functional understanding of scenes.

2. Constructing Action Maps

Our goal is to build Action Maps that associate possible actions for every spatial location on a map over a large environment. We decompose the process into three steps. We first build a physical map of the environment by using egocentric videos to obtain a 3D reconstruction of the scene using structure from motion. Second, we use a collection of recorded human activity videos recorded with an egocentric camera to detect and spatially localize actions. This collection of videos is also used to learn the visual context of actions (i.e., scene appearance and object detections) which is later used as a source of side information for modeling and inference. Third, we aggregate the localized action detection and visual context data using a matrix completion framework to generate the final Action Map. The focus of our method is the third step, which we describe next. We mention how we obtain the visual context in Section 2.1.1 and describe the first two steps in detail in Section 3.2.

2.1. Action Map Prediction as Matrix Factorization

We now describe our method for integrating the sparse set of localized actions and visual side-information to generate a dense Action Map (AM) using regularized matrix completion. Our goal is to recover an AM in matrix form \( R \in \mathbb{R}_{+}^{M \times A} \), where \( M \) is the number of locations on the discretized ground plane and \( A \) is the number of possible actions. Each row of the AM matrix \( R \) contains the action scores \( r_{ma} \), where \( m \) is a location index, and each entry \( r_{ma} \) describes the extent to which an action \( a \) can be performed at location \( m \). To complete the missing entries of \( R \), we design a similarity metric for our side-information, enabling the method to model the relationship between activities, scenes, and objects.

We impose structure on the rows and columns of the AM matrix by computing similarity scores with the side-information. Examples of this side information are shown in Figure 3, where two features from scene classification, plus one feature from object detection are shown in the same physical space as the AM. Figure 3 serves to further motivate the idea of exploiting scene and object information between two different scenes to relate the functionality of the scenes. We define three kernel functions based on scene appearance, object detections and spatial continuity. This structure is integrated as regularization in the RWNMF objective function (Equation 2).

2.1.1 Integrating Side-Information

To integrate side-information into our formulation, we build two weighted graphs that describe the cross-location (row) similarities, and cross-action (column) similarities. We are primarily interested in the cross-location similarities, and discuss how we handle the cross-action similarities in Section 2.2. To build the cross-location graph, we aggregate the spatial proximity, scene-classification, and object detection information as a linear combination of kernel-based similarities, as shown in Equation 1.

For every location \( a \) in the AM, we compute the scene classification score \( p_a = [p_{1a} \ldots p_{Ca}] \) for each image as
the average of the $C$-dimensional outputs from the Places-CNN of images within a small radius.

We use Structure-from-Motion (SFM) keypoints inside each detection to estimate the back-projected 3D location of the detected object in the environment by taking the mean of their 3D locations, which are then projected to the ground plane to form a set $D_f$ for each object category $f \in [1 \ldots F]$. The SFM reconstruction is also used to localize images and described further in Section 3.2. We calculate the object detection scores $o_k = [o_{1a} \ldots o_{Fa}]$ for each location $a$ as the max score of object detection of the nearby back-projected object detections $d \in D_f$ within a $r = \sqrt{2}$ grid-cell radius, exponentially weighted by its distance along the floor from the object $z_d$:

$$o_f = \max_{d \in D_f} \frac{1}{\sqrt{2r^2 \pi}} \exp \left( -\frac{z_d^2}{2r^2} \right).$$

We wish to enforce similarity of activities between nearby locations, as well as between locations that have similar object detections and scene classification description. Between any two locations $a$, $b$, and given associated scene classification scores $p_a$, $p_b$, object detection scores $o_a$, $o_b$, and 2D grid locations $x_a$, $x_b$, the kernel is of the form:

$$k(a, b) = (1 - \alpha)k_s(x_a, x_b) + \frac{\alpha}{2}k_p(p_a, p_b) + \frac{\alpha}{2}k_o(o_a, o_b), \quad (1)$$

where $k_s$ is an RBF kernel between the spatial coordinates of each location, $k_p$ and $k_o$ as $\chi^2$ kernels on scene classification scores and object detection scores, and $k_o$ has 0 similarity between locations with no object score.

Thus, there is a tradeoff between the $k_s$, $k_p$ and $k_o$ kernels, controlled by $\alpha$. When $\alpha = 0$, only spatial smoothness is considered, and when $\alpha = 1$, only scene classification and object detection terms are considered, ignoring spatial smoothness. When a location in one scene is compared to a location in a new scene or the same scene, $k(\cdot, \cdot)$ returns higher scores for locations with similar objects and places, and as shown Section 2.2, places more regularization constraint on the objective function, rewarding solutions that predict similar functionalities for both locations.

2.2. Completing the Action Map Matrix

To build our model, we seek to minimize the RWNMF objective function in Equation 2:

$$J(U, V) = \|W \circ (R - UV^T)\|_F^2 + \frac{\lambda}{2} \sum_{i,j} \|u_i - u_j\| \cdot K_{ij}^U + \frac{\mu}{2} \sum_{i,j} \|v_i - v_j\| \cdot K_{ij}^V \quad (2)$$

where $U \in \mathbb{R}^{M \times D}$, $V \in \mathbb{R}^{A \times D}$, together form the decomposition, $W \in \mathbb{R}^{M \times A}$ is the weight matrix with 0s for unexplored locations, and $K^U$ the kernel Gram matrix of the side information defined by its elements: $K_{ij}^U = k(i, j)$. The squared-loss term penalizes decompositions with values different from the observed values in $R$. The term involving $K^U$ penalizes decompositions in which highly similar locations have different decompositions in the rows ($u_i^T$) of $U$. Roughly, locations with high similarity in scene appearance, object presence, or position impose penalty on the resulting decomposition for predicting different affordance values in the AM. The term involving $K^V$ corresponds to the cross-action smoothing, which we take as the
identity matrix, enforcing no penalty for differences across per-location action labels.

To minimize the objective function, we use the regularized multiplicative update rules following [7]. Multiplicative update schemes for NMF are generally constructed such that their iterative application yields a non-increasing update to the objective function: [7] showed that these update rules yield non-increasing updates to the objective function. Thus, after enough iterations, a local minima in the objective function is found, and the resulting decomposition and its predictions are returned.

Values in W are set to counteract class imbalance. The number of observed values for each activity is computed as \( n_r = \frac{\text{# cells with non-empty actions}}{\text{# total cells}} \), and the zeros from observed cameras associated with no activities as \( w = \frac{1}{n_z} \).

### 3. Experiments

Our dataset consists of 5 large, multi-room scenes from various locations. Three scenes, Office Flr. A, Office Flr. D, and Office Flr. C, are taken from three distinct office buildings in the United States, and another scene, Office Flr. B, comes from an office building in Japan. Each office scene has standard office rooms, common rooms, and a small kitchen area. A final scene, Home A, consists a kitchen, a living room, and a dining room. See Table 1 for scene activity and sparsity statistics. Our goal is to predict dense Action Maps from sparse activity demonstrations.

The first experiments (Section 3.3) measure our method’s performance when supplied with all observed action data that covers on average about half of all locations and some actions (See Table 1 for the coverage statistics). Additionally, this experiments compares against performance of the spatial kernel-only approach, which serves to illustrate the utility of including side-information. However, as it takes some time to collect the observations of each scene, we demonstrate a second set of experiments (Section 3.4), to showcase our method handling fractions of the already sparse observation data while still maintaining reasonable performance. In Section 3.5, our third set of experiments shows that if our method is presented with novel scenes for which there is zero activity demonstrations, our method can still make predictions in these new environments. This final set of experiments also investigates which side-information is most helpful for our task.

#### 3.1. Performance scoring

To evaluate an AM, we perform binary classification across all activities and compute mean F1 scores. We collect the ground truth activity classes for every image in the scene by retrieving them from labelled grid cells, as shown in Figure 5, in a small triangle in front of each camera, which represents the viewable space. We collect the predicted AM scores from the same grid cells and average the scores to produce per-image AM scores. We used 100 evenly-spaced thresholds to evaluate binary classification performance by averaging F1 scores across the thresholds. We report F1 scores as opposed to the overall accuracy, as the overall accuracy of our method is very high due to the large amount of space in each scene with no labelled functionality (a large amount of “true negatives”). The activity classes we use are sit, type, open-door, read,

Table 2: Prediction results by using the activity observations for each scene (“sng”), and, as separate results, by simultaneously fitting data from all scenes (“all”). By using observations from all scenes, the performance of our method on each scene improves over using each scene’s observation data alone. Additionally, our method is able to integrate activity detections without much performance loss: a D suffix indicates activity detection predictions were used, otherwise, labelled activities were used. “S” stands for spatial kernel only, and “SOP” stands for “Spatial+Object Detection+Scene Classification” kernels. The spatial kernel only is useful yet outperformed by the full model. Side information from multiple scenes generally improves the performance.
Figure 4: Performance improves a function of available data. For each parameter setting, we show the $F_1$ scores for each activity label, as well as the mean and weighted mean of the $F_1$ scores across all parameter settings and activity labels. Some variations in performance are observed as new activities are introduced, as the correlations between an established activity and newly introduced activities are initially sparse. As more data is collected, erroneous correlations are unlearnt, and correct ones are reinforced.

Table 3: Performance of our algorithm by using activity observations from Office Flr. A to make predictions in novel scenes. Each baseline method is run with a single parameter setting, and thus their maxes and means are equivalent. The baseline methods “RFC”, “Det.”, and “NMF” correspond to the Random Forest Classification, Object Detection AMs, and non-regularized NMF augmented matrix approaches, respectively. Variants of our approach, SO, SP, and SOP correspond to using “Spatial+Object Detection” kernels, “Spatial+Scene Classification” kernels, and “Spatial+Object Detection+Scene Classification” kernels. Multiple metrics are considered to observe the effects of ground-truth class imbalance, and means are used to quantify performance across a variety of parameter settings.

3.2. Preprocessing and parameters

The first step to build the AM is to build a physical map of the environment. We use Structure-From-Motion (SFM) [19] with egocentric videos of a walk through of the environment to obtain a 3D reconstruction of the scene. Next, we consider two important categories of detectable actions: (1) those that involve the user’s hands (gesture-based activities), and (2) those that involve significant motion of the user’s head, or egomotion-based activities. We used the deep network architecture inspired by [17] to perform activity detection, as the two stream network takes into account both appearance (e.g., hands and objects) as well as motion (e.g., optical flow induced by ego-motion and local hand-object manipulations). When actions are detected by our action recognition module, we need a method for estimating the location of this action. We use the SFM model to compute the 3D camera pose of new images.

As we define an AM over a 2D ground plane (floor layout), we project the 3D camera pose associated to an action onto the ground plane. To obtain a ground plane estimate, we fit a plane to a collection of localized cameras using SFM. We assume that the egocentric camera lies approximately at eye level, thus this height plane is tangent to the top of the camera wearer’s head. We then translate this plane along its normal, while iteratively refitting planes with RANSAC to points in the SFM model. Once we have an estimate of the 2D ground plane in 3D space, we can use it to project
When dealing with multiple scenes, distances must be calibrated between them. We use prior knowledge of the user’s height to form estimates of the absolute scale of each scene. Specifically, we use the distance between the ground plane and the user height plane, along with a known user height, to convert distances in the reconstruction to meters. Finally, we grid each scene with cells of size 0.25 meters.

Since actions are often strongly correlated with the surrounding area and objects, as shown in Figure 3, we also extract the visual context of each action as a source of side-information. For every image obtained with the wearable camera, we run scene classification and object detection with [22] and [6]. We use the pre-trained “Places205-GoogLeNet” model for scene-classification, which yields 205 features per image, one per each scene type, and a radius of 2 grid cells inside which to average the classification scores. For object detection, we use the pretrained “Bvlc_reference_rcnn_ilsvrc13” model, which performs object detection for 205 different object categories, and use NMS with overlap ratio 0.3, and min detection score 0.5.

We use a small grid of parameters for our method \((\alpha \in [0, .1, .3, .5, .7, .9, 1], \lambda \in [10^{-3}, 10^{-2}], \gamma \in [100, 1000])\), where each \(\gamma\) is used for the \(\chi^2\) kernels, and evaluate performance of multiple runs as the cross-run maximum and cross-run average of each of the various scores. In a scenario with many additional test scenes, a single choice of parameters could be selected via cross-validation. We also consider variations of our kernel that use different combinations of side-information: Spatial+object detection (SO), Spatial+scene classification (SP), and Spatial+object detection+scene classification (SOP). In the first two cases, the \(\frac{1}{2}\) weight of Equation 1 becomes \(\alpha\) for the object detection or scene classification kernel that is on, and 0 for the other.

### 3.3. Full observation experiments

When all activity observations are available, our method is able to perform quite well. The dominant source of error is that of camera localization, which reduces the spatial precision of the AM. In Table 2, we evaluate the performance of our method run on each scene separately, as well as running once with all of the scenes in a single matrix. When multiple scenes are used, side-information is crucial: without it, there is no similarity enforced across scenes. In single scene case, we find that using a spatial kernel only can perform well, yet is generally outperformed by using all side information, especially when side information and activity demonstrations are present from other scenes. By using the data from all scenes simultaneously in a global factorization, performance increases globally over using each single scene’s data alone. This is expected and desirable: simultaneous understanding of multiple scenes can improve as the set of available scenes with observation data grows.

### 3.4. Partial observation experiments

We expose our algorithm to various fractions of the total activity demonstrations to simulate an increasing amount of observed actions. We find that performance is high even with only a few demonstrations and steadily increases as the amount of activity demonstrations increases. The Office Flr. A, Office Flr. D, and Home A scenes have enough activity demonstration data to illustrate the performance gains of our method as a function of the available data. We show quantitative per-class results for these in Figure 4. Sharp increases can be observed in the per-class trends, which correspond to the increase of coverage of each activity class.

In Figure 6, we show the overhead view of the AM for the sit and type labels for the Office Flr. A as a function of the available data, where it can be seen how the AM quali-
tatively improves over time as observations are collected.

3.5. Novel scene experiments

Another scenario is the task of predicting AMs for novel scenes containing zero activity observation data. Our method leverages the appearance and activity observation data in one scene, and only appearance data in the novel scene to make predictions. We now introduce three baselines we consider. The first baseline is to perform per-image classification with the object detection and scene classification features, which serves to estimate image-wise performance of using the object detection and scene classification information. This baseline requires observations in a labelled scene for training. We use Random Forests [1] as the classification method, trained on images from the source scene. The second baseline we consider is non-regularized Weighted Nonnegative Matrix Factorization by augmenting the target matrix $R$ with the object detection and scene classification features for each location. This baseline does not explicitly enforce the similarity that the regularized framework does, thus, we expect it to not perform as well as our framework. The third baseline we consider is to build AMs from the back-projected object detections by directly associating each detection category with an activity category.

We use the Office Flr. A demonstration and appearance data as input and evaluate the performance by applying the learned model to each of the other scenes. These results (Table 3) illustrate that our method’s AM predictions outperform the baselines in $\frac{13}{15}$ cases, and that the appearance information is capitalized upon the most by our method. We find that scene classification is particularly beneficial to performance, a phenomenon for which we present two hypothesized factors: 1) as shown in [21] “object detectors emerge in deep scene CNNs”, suggesting that the Scene Classification features subsume the cues present in the object detector features, and 2) due to localization noise, correlations between localized activities and localized objects are not as strong, and can serve to introduce noise to the Spatial+Scene Classification kernel combination when this object information is integrated.

Overall, we find that our model harnesses the power of activity observations in concert with the availability of rich scene classification and object detection information to estimate the functionality of environments both with and without activity observations. See the Supplementary Material for additional novel scene experiments.

4. Action Maps for Localization

We demonstrate a proof-of-concept application of Action Maps to the task of localization. Intuitively, by leveraging the “where an activity can be done” functional-spatial information from Action Maps, along with “what activity has been done” functional information from activity detection, the user’s spatial location is constrained to be in one of several areas. We localize activity sequences in each 2D map based on the combination of predicted action locations from the Action Map, and observed actions in each frame. In Figure 7, we show the spatial discrepancy in grid cells between the $K$-best AM location guesses decreases. Thus, an Action Map can be used to localize a person with observations of their activity.

5. Conclusion

We have demonstrated a novel method for generating functional maps of uninstrumented common environments. Our model jointly considers scene appearance and functionality while consolidating evidence from the natural vantage point of the user, and is able to learn from a user’s demonstrations to make predictions of functionality of less explored and completely novel areas. Finally, our proof-of-concept application hints at the breadth of future work that can exploit the rich spatial and functional information present in Action Maps.
