Fig. 1. We develop a numerical scheme for optimizing surface geometry while avoiding self-intersections. Here, we automatically find an unexpected transition between linked and unlinked states of a pair of “handcuffs” by simply minimizing a repulsive energy.

Functionals that penalize bending or stretching of a surface play a key role in geometric and scientific computing, but to date have ignored a very basic requirement: in many situations, surfaces must not pass through themselves or each other. This paper develops a numerical framework for optimization of surface geometry while avoiding (self-)collision. The starting point is the tangent-point energy, which effectively pushes apart pairs of points that are close in space but distant along the surface. We develop a discretization of this energy for triangle meshes, and introduce a novel acceleration scheme based on a fractional Sobolev inner product. In contrast to similar schemes developed for curves, we avoid the complexity of building a multiresolution mesh hierarchy by decomposing our preconditioner into two ordinary Poisson equations, plus forward application of a fractional differential operator. We further accelerate this scheme via hierarchical approximation, and describe how to incorporate a variety of constraints (on area, volume, etc.). Finally, we explore how this machinery might be applied to problems in mathematical visualization, geometric modeling, and geometry processing.

1 INTRODUCTION AND RELATED WORK

A geometric functional assigns a real-valued score $E(f)$ to each immersion $f : M \rightarrow \mathbb{R}^m$ of a surface $M$. Such functionals serve as regularizers in many geometric problems, helping to define a unique solution, or simply making the geometry “nicer” in some sense. For instance, in geometric modeling they are used to smoothly interpolate given boundary data [Bucur and Butazzo 2006], in mathematical visualization they can be used to endow an abstract surface with a concrete geometry [Chern et al. 2018], and in digital geometry processing they are used for, e.g., hole filling [Clarenz et al. 2004] or denoising of measured data [Elsey and Esedoḡlu 2009]. However, classic functionals ignore a basic requirement of many applications—namely, that surfaces should not exhibit (self-)intersections. This condition is critical when surfaces represent physical membranes (e.g., in biological simulation), boundaries of solid objects (e.g., for digital manufacturing), or certain mathematical objects (e.g., isotopy classes of embeddings). It is therefore surprising that, to date, there has been little focus on interpenetration in variational surface modeling. We build on the recent framework of Yu et al. [2021], extending their machinery for repulsive curves to the more computationally demanding case of surfaces.

Curvature Functionals. A basic functional for surfaces is total surface area; gradient descent on area leads to mean curvature flow, which has been used for surface denoising [Deshbrun et al. 1999] but can develop non-smooth singularities or pinch-off artifacts. Though...
efforts have been made to desingularize this flow [Kazhdan et al. 2012], sharp peaks and cusps are ultimately impossible to detect from area alone. For this reason, functionals used in geometric modeling typically incorporate curvature information—most prominently the Willmore energy $E_W(f) := \int_M (H^2 - K) \, dA$, where $H$ and $K$ are the mean and Gaussian curvatures, resp. Significant work has focused on numerical optimization of Willmore energy [Droske and Rumpf 2004; Bobenko and Schröder 2005; Crane et al. 2013b; Soliman et al. 2021], but since this energy is Möbius invariant, it effectively provides a notion of regularity for surfaces in the 3-sphere $S^3$, rather than the Euclidean $\mathbb{R}^3$. In the context of geometric modeling, this means that even minimizers of Willmore energy can have poor distributions of curvature—see for example Fig. 4, bottom left. Though further energies have been developed to address such issues [Moreton and Séquin 1992; Joshi and Séquin 2007], none of these energies avoid intersections.

Repulsive Forces. Collision response from physical simulation [Bridson et al. 2002] and contact mechanics [Wriggers and Zavarise 2004; Harmon et al. 2009] can be used to locally resolve contact, but does not help guide shape optimization toward a state that is far from interpretation. Moreover, whereas level set methods ensure (by construction) that surfaces have no self-intersections, the raison d’être of such methods is to allow the surface topology to change, rather than to preserve it [Osher and Fedkiw 2006]. We instead consider "all-pairs" energies of the form

$$E(f) = \int_{M \times M} k(x, y) \, dx_f \, dy_f,$$

where $dx_f$ denotes the area element induced by $f$, and the kernel $k : M \times M \rightarrow \mathbb{R}$ is designed to discourage self-contact. A tempting choice is a Coulomb-like potential

$$k_{\text{Coulomb}}(x; y) = \frac{1}{|f(x) - f(y)|^\alpha}$$

for some falloff parameter $\alpha > 0$. On a triangle mesh, this amounts to penalizing the distance between all pairs of vertices. However, as noted by Yu et al. [2021, Section 3.1], this energy is too weak to prevent collision for $\alpha < 2$ (i.e., intersecting surfaces have finite energy), and yet ill-defined in the continuum limit for $\alpha \geq 1$. The issue is that there are always points $y$ within an arbitrarily small geodesic distance $d(x, y) \geq |f(x) - f(y)|$ of any point $x \in M$, causing the energy to blow up. Numerically, ad-hoc vertex-vertex penalties are hence unstable and highly unpredictable (Fig. 2).

For curves, [O’Hara 1991] regularizes the Coulomb-like potential by subtracting the contribution of points that are nearby on the curve:

$$k_{\text{Möbius}}(x; y) = \frac{1}{|f(x) - f(y)|^2} - \frac{1}{d(x, y)^2}.$$

The resulting energy is well-defined and strong enough to prevent collisions; it is referred as Möbius energy because it is invariant under Möbius transformations [Freedman et al. 1994]. However, Möbius invariance is actually a significant drawback for geometric modeling: it leads not only to uneven curvature ([Kusner and Sullivan 1998, Figure 5]), but also "tight spots" where points distant in $S^3$ become arbitrarily close when projected into $\mathbb{R}^3$ (see [Yu et al. 2021, Figure 3]). Moreover, the geodesic distance $d(x, y)$, though easy to compute for curves, is prohibitively expensive to compute for all pairs of points on a surface—much less to differentiate with respect to motions of the surface.

Tangent-Point Energy. For all these reasons, we instead consider the tangent-point energy introduced for curves by [Buck and Orloff 1995], and only recently extended to higher dimensions by [Strzalecki and von der Mosel 2013]. For each pair of points $x, y \in M$, consider the radius $r(x, y)$ of the smallest sphere tangent to $x$ and passing through $y$, penalizing $1/r(x, y)$. Hence, the contribution will be very large for points $y$ close in space but distant along the surface—and small for points $z$ nearby along the surface, where the radius is huge.

For each pair of points $x, y$ on the surface, the tangent-point energy considers the radius $r(x, y)$ of the smallest sphere tangent to $x$ and passing through $y$, penalizing $1/r(x, y)$. Hence, the contribution will be very large for points $y$ close in space but distant along the surface—and small for points $z$ nearby along the surface, where the radius is huge.
1.1 Contributions

Overall, in this paper we develop

- the first discretization of tangent-point energy for surfaces,
- a novel preconditioner that avoids a multigrid hierarchy,
- a hierarchical solver that scales to large meshes, and
- a framework for handling auxiliary constraints and penalties.

We also perform a preliminary investigation of applications in geometric modeling, mathematical visualization, and geometry processing. Notably, although one can prove that minimizers of the tangent-point energy exist [Kolasiński et al. 2015, Theorem 2], these proofs are non-constructive. Since we provide the first discretization and optimization procedure for the tangent-point energy on surfaces, we obtain the very first glimpse (experimentally) at what some of these surfaces might actually look like.

We begin by defining our problem in the smooth setting (Sec. 2), followed by a novel discretization of the tangent-point energy and a basic numerical strategy for minimizing it subject to constraints (Sec. 3). We then significantly accelerate this strategy in two distinct ways. First, we choose an inner product in the smooth setting that vastly improves the convergence of the gradient flow (Sec. 2.4). Second, in the discrete setting, we propose a preconditioner that dramatically reduces the cost of solving for the descent step (Sec. 5).

We also accelerate evaluation of the energy and its derivatives, as well as dense matrix-vector products, using hierarchical acceleration (Sections 4 and 5). We then consider dynamic remeshing (Sec. 6) and auxiliary penalties and constraints (Sec. 7), which enable a variety of potential applications (Sec. 9); Sec. 8 provides numerical validation.

2 SMOOTH FORMULATION

In this section we define the smooth tangent-point energy $\mathcal{E}_P$, and give some remarks on the order of derivatives appearing in its differential $d\mathcal{E}_P$. Knowing the order of the differential is essential for accelerating the gradient flow $\frac{d}{dt} f = -d\mathcal{E}_P(f)$, since it enables us to define a new inner product (in Sec. 2.4) with respect to which gradient flow effectively becomes a 0th-order equation. (Readers may wish to consult Yu et al. [2021, Section 4.1] for a slower-paced, didactic introduction to this approach.) Hence, the integrator developed in Sec. 3 will be able to take dramatically larger time steps whose size does not depend strongly on mesh resolution (Fig. 5).

2.1 Energy

As discussed in Sec. 1, we can define a repulsive energy by considering the tangent-point radius $r_f(x, y)$, defined as the radius of the smallest sphere tangent to $f(x)$ and passing through $f(y)$ (Fig. 3). Letting $N_f(x)$ be the unit normal at $x$, this radius can be computed as

$$r_f(x, y) = \frac{|f(x) - f(y)|^2}{2|P_f(x)(f(x) - f(y))|}, \tag{1}$$

where $P_f(x) = N_f(x)N_f(x)^T$ denotes the orthogonal projector onto the normal space at $x$. Note that expressing $r_f$ via the projector avoids picking a sign for the normal, which will be useful in Sec. 5.1 (it is also valid for submanifolds of arbitrary dimension and codimension). Omitting the constant factor 2, the tangent-point kernel
While in principle it is possible to allow the exponents in the nu-
merator and denominator to vary independently [Blatt and Reiter
2015], we use exponents $p, 2p$ (as above), which simplifies analysis.
Note that, because $k_{f,p}$ has units $m^{-p}$ (in meters) and $\mathcal{E}^p$ is a
double integral over an $n$-dimensional manifold, $\mathcal{E}^p$ has units $m^{2n-p}$.
Therefore, $p > 2n$ is required for the energy to be truly repulsive
(i.e., to have units corresponding to inverse meters); otherwise, the
energy could be reduced to $0$ by simply shrinking the domain to a
single point. As we deal with surfaces here ($n = 2$), $p > 4$ is sufficient.
Unless otherwise noted, we use $p = 6$ for all examples in this paper.

### 2.2 Gradient Flow

Attempting to perform standard $L^2$ gradient descent on the tangent-
point energy yields a flow

$$\frac{d}{dt} f = -A^{-1} d\mathcal{E}^p(f).$$

An optimal choice of $A$ will match the order of the differential, so that
the right hand side no longer involves any spatial derivatives (hence
avoiding a mesh-based time step restriction). We first establish the
order of the differential $d\mathcal{E}^p$ in the surface case (Sec. 2.3), then define
a fractional Sobolev inner product that matches this order (Sec. 2.2).

#### 2.3 Order of the Differential

Though originally defined for curves, the tangent-point energy $\mathcal{E}^p$
can be formulated for a quite broad class of $n$-dimensional sets $\Sigma \subset \mathbb{R}^m$ 
“with tangent planes,” that need not even be manifolds [Strze-
lecki and von der Mosel 2013]. In the case of 2-dimensional surfaces,
one can argue (as discussed below) that $d\mathcal{E}^p$ is a nonlocal, nonlinear
differential operator of fractional order $2(2 - 2/p) \in [3, 4]$, rather
than integer order. This distinguishes the tangent-point energy from
standard geometric energies like Willmore, and it is why we have
to develop special tools for it.

In more detail: Strzelecki and von der Mosel [2013] show that
if tangent-point energy is finite for some $n$-dimensional $\Sigma \subset \mathbb{R}^m$, then $\Sigma$
must be an embedded submanifold of Hölder class $C^{1,\alpha}$, where $\alpha = 2 - 2n/p$. Intuitively: it must be free of self-intersections,
and also fairly regular. This result is improved by [Blatt 2013], who
establishes that $\mathcal{E}^p(\Sigma)$ is finite if and only if $\Sigma$ is an embedded
submanifold of fractional Sobolev class $W^{s,p}$, where $s = 2 - n/p$. In
particular, this implies that $\Sigma$ can be expressed as an embedding
$f \in W^{s,p}(M; \mathbb{R}^m)$ for some smooth manifold $M$. For $n = 2$ we have
$s \in [3/2, 2]$, so we inevitably have to deal with fractional Sobolev
spaces. Knowing the natural habitat of $\mathcal{E}^p$ is key because it allows for
the following observation: the differential $d\mathcal{E}^p$ is a mapping from
While this formula only relates to $\Delta^s$ within a finite time. The kernel inner product that consider throughout this work. The order of this inner product matches that of the Sobolev space and so distant (if not infinitely so) that they are unlikely to be reached better preconditioning in situations with close contact by adding More precisely, we use numerator, yielding a higher-order operator is outside the bounds $p$, which can be expressed in integral form up to a constant factor as
\[
\langle (-\Delta)^s u, v \rangle_{L^2} = \int \frac{(u(x) - u(y))(v(x) - v(y))}{|x - y|^{2s+2}} \, dx \, dy
\]  
(5)
for sufficiently smooth functions $u, v : \mathbb{R}^n \to \mathbb{R}$ [Kwaśnicki 2017].

While this formula only relates to $\mathbb{R}^n$, we can obtain an analogous operator $L^\sigma$ of fractional order $2\sigma$ on functions $u, v : M \to \mathbb{R}$ by mimicking this expression on the $n$-dimensional manifold $M$:
\[
\langle L^\sigma u, v \rangle_{L^2} = \int_{M^2} \frac{(u(x) - u(y))(v(x) - v(y))}{|f(x) - f(y)|^{2\sigma+2}} \, dx \, dy.
\]  
(6)

Note that, for $p > 2n$, the order of $dE^\sigma$ is $2\sigma = (2 - n/p) > 3$, which is outside the bounds $0 < 2\sigma < 2$. We can increase the order of this operator by introducing a first order derivative operator $D_f$ in the numerator, yielding a higher-order operator
\[
\langle Bu, v \rangle_{L^2} = \int_{M^2} \frac{D_f u(x) - D_f u(y))(v(x) - v(y))}{|f(x) - f(y)|^{2\sigma+2}} \, dx \, dy.
\]  
(7)

More precisely, we use $D_f u(x) := du(x)/df(x)$, where $df(x)$ denotes the Moore-Penrose pseudo-inverse of $df(x)$. If we now set $\sigma = s - 1$, then the operator $B$ achieves the desired order $2s$.

Low order term. As proposed by Yu et al. [2021], we can get even better preconditioning in situations with close contact by adding an additional term of lower order, which we can obtain translates to
\[
\langle B_0 u, v \rangle_{L^2} = \int_{M^2} \frac{(u(x) - u(y))(v(x) - v(y))}{|f(x) - f(y)|^{2\sigma+2}} \, dx \, dy.
\]  
(8)

The inclusion of the tangent-point kernel $k_f(x, y)$ effectively distorts lengths in regions of high energy: as the local energy increases, so too does the apparent length induced by the inner product. As a result, self-intersecting configurations, having infinite energy, are so distant (if not infinitely so) that they are unlikely to be reached within a finite time. The kernel $k_f(x, y)$ is chosen here so that $B$ and $B_0$ have the same units and thus behave similarly under scaling.

The overall operator $A = B + B_0$ then defines a positive-semidefinite inner product that consider throughout this work. The order of this inner product matches that of the Sobolev space $W^{s,2} = H^s$, hence we use the term $H^s$ to refer to our fractional preconditioner.

### 3 DISCRETIZATION

We next discretize all components needed for our optimization scheme. The basic idea is to minimize tangent-point energy via gradient descent, preconditioned by our fractional inner product. In practice we also want to incorporate constraints, which we do by projecting the descent direction onto the tangent space of the constraint manifold, then projecting the surface itself onto this manifold. The overall algorithm for each descent step is:

#### ALGORITHM 1: Assembly of the exact discrete fractional operator $L^\sigma$

1. Assemble the derivative $dE^\sigma(f)$ of the energy (Sec. 3.1).
2. Construct the fractional operator $A = B + B_0$ (Sec. 3.2).
3. Solve Eq. 14 to obtain the descent direction $x$.
4. Take a step in the direction $x$ using Armijo line search.
5. Project onto the constraint manifold of $\Phi$ (Sec. 3.3.2).

This initial algorithm is quite inefficient, and is accelerated in Sections 4 and 5. Sec. 5.4 gives the final accelerated algorithm.

#### 3.1 Discrete Energy

On a triangle mesh $M = (V, E, F)$ with vertex coordinates $f : V \to \mathbb{R}^3$, we approximate the energy $E^\sigma$ (Eq. 3) using midpoint quadrature. In particular, we define the discrete tangent-point kernel on a pair of faces $S, T \in F$ as
\[
K_{f,\sigma}(S, T) = \frac{|P_f(S)(X_f(S) - X_f(T))|^p}{|X_f(S) - X_f(T)|^{|p+2}},
\]  
(9)

where $X_f(S)$ denotes the barycenter of face $S$ for an embedding $f$. The full energy is then defined as a double sum
\[
E^\sigma(f) = \sum_{S \in F} \sum_{T \in F} K_{f,\sigma}(S, T) a_f(S) a_f(T),
\]  
(10)

where $a_f(S)$ denotes the area of face $S$ under embedding $f$. The differential $dE^\sigma(f)$ is then just the vector of partial derivatives of the discrete energy $E^\sigma$ with respect to $f$ in $\mathbb{R}^3|V|$, which can be evaluated via any standard technique.

#### 3.2 Discrete Inner Product

The fractional operator $L^\sigma$ is discretized as a $|V| \times |V|$ matrix with entries obtained from the right-hand side of Eq. 6. The rows and columns of $L^\sigma$ are indexed by vertices, with entries
\[
L_{ij}^\sigma = \sum_{S \in F \in T \in F} \frac{(\hat{\phi}_i(S) - \hat{\phi}_i(T))(\hat{\phi}_j(S) - \hat{\phi}_j(T))}{|X_f(S) - X_f(T)|^{2\sigma+2}} a_f(S) a_f(T),
\]  
(11)

where $\hat{\phi}_i$ denotes the piecewise linear hat-function centered at vertex $i$, and where $\hat{\phi}_i(S)$ denotes its evaluation on the barycenter of $S$, i.e., $\hat{\phi}_i(S)$ is 1/3 if vertex $i$ is contained in face $S$ and 0 otherwise. A naïve entry-by-entry assembly of $L^\sigma$ via Eq. 11 would take time quartic in the number of mesh elements; however, since the summand vanishes for most pairs $S, T$, assembly can be done in quadratic time by iterating over mesh elements rather than matrix entries—see Alg. 1.
3.2.1 High- and Low-Order Terms. The high-order term of our discrete inner product $B \in \mathbb{R}^{|V| \times |V|}$ (corresponding to Eq. 7) is also assembled via Alg. 1, but using the summand
\[
\frac{(D_f \hat{\Phi}_t(S)) - D_f \hat{\Phi}_t(T))}{|X_f(S) - X_f(T)|^{2\sigma + 2}} = a_f(S) a_f(T) \tag{12}
\]
for $i$ in the one in Eq. 11. Here $D_f$ is a discretization of $D_f$. Intuitively, $D_f(S)$ is the derivative of the function $u = \sum_{i \in V} u_i \hat{\phi}_i$ within the triangle $S$, and can be evaluated as
\[
\frac{1}{2a_f(S)}(N_f(S) \times (u_i e_{jk} + u_j e_{ki} + u_k e_{ij}))^T,
\]
where $i, j, k$ are the vertices of triangle $S$ and $e_{ij}, e_{jk}$, and $e_{ki}$ are the unit edge vectors of $S$. The low-order matrix $B_0 \in \mathbb{R}^{|V| \times |V|}$ is likewise assembled using the summand
\[
\frac{(\hat{\Phi}_t(S) - \hat{\Phi}_t(T))}{|X_f(S) - X_f(T)|^{2\sigma + 2}} = K_{f,2}(S, T) a_f(S) a_f(T) \tag{13}
\]
using the discrete kernel $K_{f,2}(S, T)$ from Eq. 9. We then get a $|V| \times |V|$ matrix $A = B + B_0$ which acts on scalar functions. A corresponding operator $A_3$ for vector-valued functions $u, v : V \to \mathbb{R}^3$ is obtained by replacing each entry $A_{ij}$ with the $3 \times 3$ block $A_{ij} |_{3 \times 3}$ (where $l$ is the identity), giving a matrix of size $3 |V| \times 3 |V|$.

3.3 Constraints

3.3.1 Gradient Projection. Suppose we want our surface to satisfy a constraint $\Phi(f) = 0$ for some constraint function $\Phi : \mathbb{R}^3|V| \to \mathbb{R}^k$ (e.g., to control area or volume). The constrained descent direction $x$ can be obtained by solving the saddle point problem
\[
\begin{bmatrix}
A_3 & d\Phi(f)^T \\
0 & 0
\end{bmatrix}
\begin{bmatrix}
x \\
\lambda
\end{bmatrix} =
\begin{bmatrix}
-\nabla E^P(f) \\
0
\end{bmatrix},
\tag{14}
\]
where $d\Phi(f)$ denotes the Jacobian of $\Phi$ and $\lambda \in \mathbb{R}^k$ are Lagrange multipliers. The resulting descent direction $x$ will then be tangent to the constraint manifold $\{f \mid \Phi(f) = 0\}$.

Importantly, we must always have some kind of constraint: the matrix $A_3$ has a null space corresponding to translations of the surface, which means the unconstrained system $A_3 x = -\nabla E^P(f)$ does not have a unique solution. One simple solution is to fix the barycenter (Sec. 7.1.1), though other constraints such as pinned vertices (Sec. 7.2) can serve the same purpose.

3.3.2 Corrective Projection. Though our descent direction $x$ is now tangent to the constraint manifold, the embedding $f^*$ may still drift away from the constraint manifold. Hence, after finding a feasible step size $\tau > 0$ via line search, we project the new state $f + \tau x$ back onto the constraint manifold of $\Phi$ via Newton’s method. In particular, we re-use the matrix from Eq. 14 and solve
\[
\begin{bmatrix}
A_3 & d\Phi(f)^T \\
0 & 0
\end{bmatrix}
\begin{bmatrix}
h \\
\lambda
\end{bmatrix} =
\begin{bmatrix}
0 \\
-\Phi(f + \tau x)
\end{bmatrix},
\tag{15}
\]
to obtain a Newton step $h$, which we add to the updated embedding $f + \tau x$. The step $h$ is the least-norm solution of the linear equation $d\Phi(f) h = -\Phi(f)$, with respect to the metric encoded by $A_3$. This correction can be repeated several times if the constraint violation is not sufficiently small—though for the constraints we explored a single step was always sufficient.

4 ENERGY AND DERIVATIVE EVALUATION

The algorithm of Sec. 3 is bottlenecked by several operations of at least quadratic complexity. The first bottleneck is evaluation of the energy $E^P$ and its derivatives $dE^P$, which requires iteration over all pairs of elements. We thus use hierarchical Barnes-Hut approximation [Barnes and Hut 1986] to accelerate computation.

Note that the kernel $K_{p^r}(S, T)$ (Eq. 9) involves only the barycenters of $S$ and $T$, and the normal projector of $S$. To clarify this dependence, we here write it as $K_{p^r}(X_f(S), P_f(S) ; X_f(T))$, with
\[
K_{p^r}(X, P ; Y) := \frac{|P(X - Y)|^p}{|X - Y|^{2p}}. \tag{16}
\]

4.1 Approximate Energy

At each step we construct a bounding-volume hierarchy (BVH) for the current face set, which is used to evaluate the Barnes-Hut approximation
\[
\bar{E}^P(f) = \sum_{S \in F} \sum_{T \in \text{adm}(S)} K_{p^r}(X_f(S), P_f(S) ; X_f(T)) a_f(S) a_f(T). \tag{17}
\]
Here $\text{adm}(S)$ is the set of BVH nodes $T$ that are admissible with respect to face $S$, but have no admissible ancestors. In particular, a Taylor series analysis of Eq. 16 indicates that to keep error bounded, $I$ must either (1) contain a single face, or (2) satisfy
\[
\max(r(S), r(I)) < \theta \text{ dist}(S, \text{conv}(I)),
\]
where $r(S), r(I)$ are the radii of the triangle $S$ and the node $I$, resp. (measured from their barycenters), $\theta \geq 0$ is a fixed parameter, dist is the minimum distance between sets, and conv is the convex hull.

In practice, we approximate the convex hull by the axis-aligned bounding box, leading to a stricter admissibility condition; the radius $r(I)$ is then the bounding box radius relative to the barycenter of all faces in $I$. Likewise, rather than store individual faces in BVH leaves, we stop when a node contains no more than $l$ faces ($l = 8$ in our experiments). Hence, if a leaf is not admissible, we directly sum over all its faces. Overall, each node $I$ stores the total area $a_f$, barycenter $X_f$, and axis-aligned bounding box $B_f$ of its faces.

The separation parameter $\theta$ controls the approximation quality; the higher $\theta$ is, the faster the computation, but the less accurate the result. For $\theta = 0$, the sum degenerates to an all-pairs exact computation. Unless otherwise noted, we use $\theta = 0.5$ for all experiments. Note that we do not update the energy approximation during line search, but rather just fix the admissibility of clusters at the beginning of the search.

4.2 Approximate Derivative

Computing an approximate derivative with Barnes-Hut is not entirely analogous to computing the energy. For each vertex $v \in V$, we evaluate the sum
\[
\bar{\partial_v E^P(f)} = \sum_{S \in F(v)} \sum_{T \in \text{adm}(S)} \partial_v(K_{p^r}(X_f(S), P_f(S) ; X_f(T)) a_f(S) a_f(T)),
\]
where $F(v)$ denotes the set of faces containing $v$. This approximates both the forward and reverse terms that would be differentiated by $v$ in an exact computation. Note that the outer sum over all $S \in F(v)$ for both energy and derivative evaluations can be evaluated as a parallel reduction without modification.

ACM Trans. Graph., Vol. 40, No. 6, Article 268. Publication date: December 2021.
5 ITERATIVE LINEAR SOLVER

An even more significant bottleneck than the energy is the dense saddle point problem of Eq. 14. Rather than solving this problem via dense matrix inversion, we will solve it instead using GMRES, an iterative method. In general, efficient iterative methods require two key ingredients: fast matrix-vector products, and effective preconditioners. Here, we will describe methods for both.

5.1 Hierarchical Matrices

We use hierarchical matrices [Hackbusch 2015] to perform fast multiplication with $A$ without explicitly assembling the matrix. In this section, we present the special case of rank-1 compression of kernel matrices, while noting that the original method can also perform higher-rank approximations. In our setting, a kernel matrix $H$ is a matrix of size $|F| \times |F|$ whose entries are defined by

$$H_{ST} = (1 - \delta_{ST}) h(X_T(S), P_T(S); X_T(T), P_T(S)),$$

where $h : (\mathbb{R}^m \times \text{End}(\mathbb{R}^m)) \times (\mathbb{R}^m \times \text{End}(\mathbb{R}^m)) \to \mathbb{R}$ is a suitable kernel function. To motivate this approach, we first reduce the actions of the operators $L^a$, $B$, and $B_0$ to the multiplication with certain kernel matrices.

5.1.1 Applying the operator $L^a$. An elementary computation shows (see App. A) that the action of the discrete linear operator $L^a$ on a vector $v \in \mathbb{R}^{|V|}$ can be written as

$$L^a v = 2 U^T \left[ \text{diag} \left( \text{diag}(a_f)^{-1} H a_f \right) - H \right] \bigcap v.$$

Here $a_f$ is the $|F|\times$-vector of face areas; $U$ is the $|F| \times |V|$-matrix that averages values on vertices onto faces and multiplies with the face areas; and $H$ is the kernel matrix of size $|F| \times |F|$ to the singular kernel $h(X, P; Y, Q) = |X - Y|^{-\sigma}$. $U$ is sparse, so we just need an efficient product with $H$ to evaluate the full product with $L^a$.

5.1.2 Applying the High-Order Term. To evaluate a matrix-vector product with $A = B + B_0$, it suffices to evaluate $B$ and $B_0$ separately. This can be done in a similar fashion as for $L^a$. For the higher order term $B$, we have the identity

$$B v = 2 V^T \left[ \text{diag} \left( \text{diag}(a_f)^{-1} H a_f \right) - H \right] \bigcap v,$$

where $V = \text{diag}(a_f) D_F$ with the discrete derivative operator $D_F$ described in Sec. 3.2.1 and where the kernel $h$ of the kernel matrix $H$ is given by $h(X, P; Y, Q) = |X - Y|^{-\sigma}$.

5.1.3 Applying the Low-Order Term. Likewise, we can write the action of $B_0$ as

$$B_0 v = 2 V^T \left[ \text{diag} \left( \text{diag}(a_f)^{-1} H a_f \right) - H \right] \bigcap v,$$

where the kernel $h$ of the kernel matrix $H$ is given by

$$h(X, P; Y, Q) = \frac{k_2(X, P; Y) + k_2(Y, Q; X)}{2|X - Y|^{2(\sigma - 1) + 2}}.$$

5.1.4 Block Cluster Tree. EnergyAndDerivativeEvaluation In order to compress these kernel matrices, we reuse the BVH from Sec. 4, but additionally compute the average projector $P_T := a_f^{-1} \sum_{S \in T} a_f(S) P_T(S)$ for each node $T$. From this, we construct a block cluster tree, whose nodes (termed block clusters) consist of pairs of BVH nodes (termed clusters in the following). For a given separation parameter $\chi \geq 0$, we say that two BVH clusters $I$ and $J$ are a separated pair if

$$\max(r(I), r(J)) \leq \chi \text{dist}(\text{conv}(I), \text{conv}(J)).$$

Here again, $(I), r(J)$ are the radii of the nodes $I$, $J$ as measured from their barycenters. The parameter $\chi$ controls the accuracy of the approximation; it will be discussed further in the next section. Then, denoting the BVH root by $R$, we construct the block cluster tree by starting with the single pair $(R, R)$, and iteratively splitting nonseparated nodes $(I, J)$ into the Cartesian products of their constituents' children until all leaf nodes are either separated or cannot be split any further. In practice, the tree structure is not important to maintain; only the lists of leaf nodes matter. We refer to the separated leaf nodes of the block cluster tree as admissible blocks and to the others as inadmissible blocks; Fig. 6 illustrates the decomposition of the full matrix into these blocks.

5.1.5 Hierarchical Multiplication. The block cluster tree allows us to perform approximate multiplication with a kernel matrix $H$ as follows. Every pair of BVH clusters $(I, J)$ corresponds to a block of $H$ with rows indexed by $I$ and columns by $J$. Let $H_I J$ denote this matrix block and let $x_I$ and $y_J$ denote the slices of $x \in \mathbb{R}^{|F|}$ and of the all-ones vector indexed by $I$, respectively. Then, for all leaf blocks $(I, J)$, we compute the product $y = H x$ in two steps:

1. If $(I, J)$ is inadmissible, then we multiply exactly:

$$y_I \leftarrow y_I + H_I J x_J.$$

2. If $(I, J)$ is admissible, we employ rank-one approximation:

$$y_I \leftarrow y_I + H_I J x_J.$$ Here, we can see more clearly the effect of $\chi$. For $\chi = 0$, all blocks are considered inadmissible, and the action of $H$ is evaluated exactly. For $\chi > 0$, the larger the value, the more blocks will be considered admissible and thus multiplied using the fast approximation in Step 2, leading to faster evaluation time – but also higher error, analogous to the $\theta$ parameter for Barnes-Hut. For our experiments, we found $\chi = 0.5$ to be a broadly acceptable value. Note that, while a straightforward implementation of these two steps is sufficient to evaluate the product, a much faster implementation can be obtained by employing multipole methods; see App. B for details.

5.2 Preconditioner

We can now efficiently evaluate matrix-vector products with $A$, but to efficiently solve $Ax = b$ we still need a good preconditioner for $A$, i.e., an efficient approximation of $A^{-1}$. Since we do not explicitly build $A$, classical preconditioners (e.g., diagonal or incomplete Cholesky) cannot be used.
Instead, consider the Laplace-Beltrami operator $\Delta_f$ of the embedding $f : M \to \mathbb{R}^3$, which for a triangle mesh is given by the sparse cotan-Laplace matrix [Crane et al. 2013a, Section 6.4]. Our inner product $A$ is closely related to the fractional Laplacian $(-\Delta_{M})^{s}$, and has the same order 2s. Evaluating the fractional power of a large sparse matrix is prohibitively expensive—but we can still obtain a cheap approximation of the inverse $(-\Delta_{M})^{-s}$ via the factorization $(-\Delta_{M})^{-s} = (\Delta_{M})^{-1}(-\Delta_{M})^{2s}(\Delta_{M})^{-1}$. What remains is a forward application of the fractional Laplacian $(-\Delta_{M})^{s}$, whose action can be efficiently approximated à la [2013].

Though we can now iteratively solve the system (Eq. 14) exhibits poor convergence. Hence, we instead use the Schur complement of the saddle point matrix $M$ to solve Eq. 15 for the corrective step $h$. Only the top-right block of the Schur complement is needed, giving the expression $h = -(A_3^{-1}d\Phi^T)(M/A)^{-1}(-\Phi(f))$. (21) $(M/A)$ does not need to be recomputed, and $A_3^{-1}d\Phi^T$ can again be reused. Thus, constraint projection incurs no significant costs.

5.3 Schur Complement

Though we can now iteratively solve the unconstrained problem $Ax = b$, we must still handle the constraints. Empirically, we find that applying an iterative method directly to the saddle-point system (Eq. 14) exhibits poor convergence. Hence, we instead use the Schur complement [Zhang 2005] to handle the additional rows. In particular, let $M$ be the saddle point matrix

$$M := \begin{bmatrix} A_3 & d\Phi^T \\ d\Phi & 0 \end{bmatrix}. \tag{18}$$

The Schur complement of $M$ with respect to $A_3$ is $$(M/A) = -d\Phi (A_3^{-1}d\Phi^T), \tag{19}$$

and the blocks of $M^{-1}$ can be expressed as

$$M^{-1} = \begin{bmatrix} A_3^{-1} + (A_3^{-1}d\Phi^T)(M/A_3)^{-1}d\Phi A_3^{-1} & -(A_3^{-1}d\Phi^T)(M/A)^{-1} \\ -(M/A)^{-1}(A_3^{-1}d\Phi^T)^T & (M/A)^{-1} \end{bmatrix}. \tag{18}$$

The operator $A_3^{-1}$ can be applied using the iterative method just outlined; a product with $A_3$ is equivalent to three separate products with $A$. The complement $M/A$ is dense, but has dimensions $k \times k$, corresponding to the number of scalar constraints. So, as long as $k$ is small, $(M/A)^{-1}$ can be computed quickly. Thus, all blocks of $M^{-1}$ are computed without having to invert a large matrix.

Moreover, to get the constrained descent direction $x$, we need only the top-left block: letting $g := d\Phi^T(f)$, we compute the descent direction by directly applying the top-left block to $x$, yielding

$$x = A_3^{-1}g + (A_3^{-1}d\Phi^T)(M/A)^{-1}d\Phi (A_3^{-1}g). \tag{20}$$

Eq. 19 requires one application of $A_3^{-1}$ per row of $d\Phi$. Eq. 20 contains three occurrences of $A_3^{-1}$, but $A_3^{-1}g$ can be reused in both places where it appears, and $A_3^{-1}d\Phi^T$ can be reused from its earlier computation in Eq. 19. Thus, the method requires just $k + 1$ iterative solves, where $k$ is the number of constraints.

5.3.1 Corrective Projection. We similarly use the Schur complement to solve Eq. 15 for the corrective step $h$. Only the top-right block of the Schur complement is needed, giving the expression

$$h = -(A_3^{-1}d\Phi^T)(M/A)^{-1}(-\Phi(f)). \tag{21}$$

$(M/A)$ does not need to be recomputed, and $A_3^{-1}d\Phi^T$ can again be reused. Thus, constraint projection incurs no significant costs.

5.4 Accelerated Algorithm Overview

The accelerated algorithm is as follows:

1. Assemble the (approximate) derivative $d\Phi^T(f)$ of the energy using Barnes-Hut (Sec. 4).
2. Construct a BVH that partitions the faces of the mesh, and use it to create a block cluster tree (Sec. 5.1.4).
3. Use the Schur complement to solve the constrained saddle point problem (Eq. 14).
   a. Evaluate products with $(A_3)^{-1}$ by using a matrix-free iterative method (e.g., GMRES), with the preconditioner from Sec. 5.2, and an initial guess of 0.
   b. Within the iterative method, evaluate products with $A$ using the block cluster tree (Sec. 5.1.2, Sec. 5.1.3).
4. Take a step in the direction of $x$ using standard line search.
5. Reuse the Schur complement to project the resulting embedding onto the constraint manifold of $\Phi$ (Sec. 5.3.1).

If no constraints are imposed, then the algorithm can be simplified: step 3 can be replaced by a single iterative solve $A_3x = b$, and step 5 can be omitted entirely.

6 DYNAMIC REMESHING

Minimizing the tangent-point energy often induces large surface deformations that degrade triangle quality. We therefore use a dynamic remeshing scheme similar to the approach of Chen and Holst [2011]. The exact algorithm we use is as follows:

1. Edges with length greater than 3$L_0/2$ are split and edges with length smaller than $L_0/2$ are collapsed, unless this operation would result in triangle foldover.
2. For $N$ iterations:
   a. All edges that violate the Delaunay condition are flipped until no such flippable edges can be found.
   b. Vertex positions are smoothed by computing a displacement vector from neighboring triangles $u_i = \rho \frac{\sum_{S \in F(i)} \alpha_r(S)(c_{ij}(S) - f(i))}{\sum_{S \in F(i)} \alpha_r(S)}.$

Here $F(i)$ denotes the set of faces containing vertex $i$, $c_{ij}(S)$ is the circumcenter of the triangle $S$, and $\rho < 1$ is a constant. This displacement is projected onto the tangent space of the vertex and added to the original position.
We consider four types of constraints: fixed barycenter, vertex pins, fractional Laplacian (Sec. 3.3); either a barycenter constraint or pinned vertices (3 rows per mesh component) or pinned vertices (3 rows per mesh component) or pinned vertices.

Conceptually, the corresponding matrix $A'_c$ then becomes the upper-left block of the original saddle-point matrix $M$ (Eq. 18), though in practice we work with the smaller matrix $A'_c$, since constraints on position can be separated into three independent components. The same constraint rows and columns are also appended to the integer Laplacians in the preconditioner (Sec. 5.2). A forward matrix-vector product with $A'_c$ now entails sparse products with $d\Phi_C$ and $d\Phi_p$, in addition to the usual hierarchical product with $A$ from Sec. 5.1.

Overall, this scheme enables efficient handling of Dirichlet boundary conditions (Fig. 9). Note that fast convergence in this scenario requires that orthogonality to these constraints be sufficiently similar under the two inner products defined by the integer Laplacian $A$ and the fractional operator $A$. Empirically, this is the case for linear positional constraints, but is not the case for constraints such as

**Barycenter Motions.** In some cases, it might be desirable to allow the barycenter to float freely, e.g., when a scene contains fixed obstacles for the surface to avoid. A simple modification enables this motion: compute the weighted average over all vertices of the $L^2$ gradient before projection, and then add the constant translation by that vector back to the descent direction after projection. For domains with multiple components, the average motion is computed separately for each component (Fig. 8).

**7.1.2 Vertex Pin Constraints.** A vertex pin constraint simply fixes a vertex to a position. Every pinned vertex $i$ produces a constraint function $\Phi_P(f) = f(i) - f_0(i)$, where $f_0(i)$ is the pinned position. The Jacobian $d\Phi_P$ is a $3 \times 3|V|$ matrix, but the only nonzero entries consist of a single copy of the identity matrix in the block indexed by $i$. A pin also eliminates the nullspace of the Laplacian, so if any pins are used, then a barycenter constraint is unneeded.

**7.1.3 Total Area Constraint.** A total area constraint preserves the total surface area of the mesh, and can be written as

$$\Phi_A(f) = (\sum_{T \in F} a_f(T)) - A_0,$$

where $A_0$ is the target area. The Jacobian $d\Phi_A$ is a $3|V|$ row vector with the area gradient at each vertex, which is equivalent to twice the mean curvature normal.

**7.1.4 Total Volume Constraint.** Likewise, a total (signed) volume constraint can be written as

$$\Phi_V(f) = \frac{1}{2}(\sum_{(ijk) \in F} f(i) \cdot (f(j) \times f(k))) - V_0,$$

where $V_0$ is the target volume. For each vertex, the Jacobian $d\Phi_V$ is proportional to the area-weighted vertex normal.

**7.2 Fast Positional Constraints**

As discussed in Sec. 5.3, computing the Schur complement requires one iterative solve per constraint. For constraints such as fixed barycenters (3 rows per mesh component) or pinned vertices (3 rows per vertex), these solves incur significant cost. Hence, rather than use the full-blown Schur complement to handle these simpler linear constraints, we incorporate them into the matrix $A$. More precisely, if $\Phi_Q$ describes all constraints on position, then we replace $A$ with another saddle-point matrix

$$A' := \begin{bmatrix} A & d\Phi_Q^T \\ d\Phi_Q & 0 \end{bmatrix}.$$
total area and volume. Thus, we reserve the Schur complement for these more difficult constraints.

7.3 Penalties

In addition to hard constraints, a number of soft penalty potentials can be added to regularize the flow in some way. These potentials are added directly to the objective function with some weighting coefficient alongside the tangent-point energy, and their gradients are accumulated in the same step.

7.3.1 Total Area and Volume Potentials. Soft penalties for total area and volume can be used in place of hard constraints, encouraging these quantities to stay close to their initial values without enforcing this exactly. For total area, the potential is defined as

$$E_{\text{area}}(f) = \left( \sum_{T \in F} a_f(T) / A_0 - 1 \right)^2.$$ 

The raw deviation is normalized by the initial area $A_0$ to make the penalty scale invariant. The total volume potential is defined analogously.

7.3.2 Static Obstacles. For practical modeling purposes, it may be desirable not to design an object in isolation, but instead to design it within its intended environment. To that end, we provide the ability to place “obstacles”, which are static meshes that exert a repulsive force on the optimization surface. These obstacles can be used to model surrounding environments such as rooms and the objects within them, which must be avoided by the object under design. From an obstacle $O$ with embedding $f_O$, each point $x$ in the domain experiences a repulsive potential equal to

$$E_{\text{obs}}(x) = \sum_{S \in f_O} |f_O(S) - x|^p a_{f_O}(S)$$

with $p$ matching the exponent of the tangent-point energy. Naively, this requires iteration over all faces of $O$, but Barnes-Hut can be used as in Sec. 4 to approximate the obstacle potential.

7.3.3 Implicit Obstacles and Attractors. Similarly to static mesh obstacles, one can also use implicit surfaces defined by signed distance fields as obstacles or attractors. Given a signed distance field $d : \mathbb{R}^3 \to \mathbb{R}$, the repulsive potential experienced at any point $x$ due to the implicit obstacle defined by $d(x) = 0$ is simply

$$E_d(x) = d(x)^{-p}.$$ 

An implicit attractor, rather than repelling other objects away from it, pulls objects towards it. The attractive potential experienced at any point $x$ is simply the reciprocal of the above, or

$$E_a(x) = d(x)^p.$$ 

7.3.4 Boundary Length and Curvature. For meshes with boundary (e.g. Fig. 20), it may be beneficial to regularize the shape of the boundary curves. We support two potentials for this purpose. One is a regularizer on the length of the boundary, defined as

$$E_b = (L - \sum_{e \in \partial M} l(e))^2,$$

where $L$ is a target boundary length, and $l(e)$ is the length of boundary edge $e$. The other regularizes the curvature, and is defined as

$$E_c = \sum_{v \in \partial M} \theta(v)^2 / l(v),$$

where $\theta(v)$ is the turning angle at vertex $v$, and $l(v)$ is the dual length (i.e., half the length of the two incident edges).

7.3.5 Willmore Energy. One can also add surface fairing energies such as the Willmore energy. For example, we use the following discrete variant of the squared mean curvature integral:

$$E_{\text{Willmore}}(f) = \int A \mathbf{M}^{-1} A f.$$ 

Here $A$ is the stiffness matrix of the cotan Laplacian and $M$ is the lumped mass matrix. Up to mass lumping, this is the discrete Willmore energy from [Dziuk 2008]. As suggested in [Eckstein et al. 2007; Schumacher 2017], we add an $H^2$ inner product term $A \mathbf{M}^{-1} A$ to the matrix that we invert in Sec. 5.

8 EVALUATION AND COMPARISONS

8.1 Consistency

Evaluating convergence of our discretization and approximation schemes is not straightforward, since to date there are only conjectures about what minimizers might look like (Sec. 9.1.1). Instead, we numerically study the consistency of our discretization: we generate several smooth surfaces, compute their true tangent-point energies, and compare to our discrete energy and its Barnes-Hut approximation.

The exact energy can be computed directly only for very simple shapes, like a sphere or torus of revolution. To get a more generic picture, we took the parameterized torus of revolution $f_0(\phi, \theta) = ((1 + \frac{1}{2} \cos(\phi)) \cos(\theta), (1 + \frac{1}{2} \cos(\theta)) \sin(\phi), \frac{1}{2} \sin(\theta))$ and perturbed it by a random trigonometric polynomial $\Phi : \mathbb{R}^3 \to \mathbb{R}^3$ of small magnitude (to ensure embeddedness) and small order (to obtain moderate curvature), obtaining a final smooth surface $f := f_0 + \Phi \circ f_0$. We computed $E(f)$ up to 6 digits of precision via numerical integration with Mathematica’s NIntegrate command using the “LocalAdaptive” strategy. We then computed an affinely squeezed Delaunay triangulation of $[0, 2\pi] \times [0, 2\pi]$ and used it to sample the surface $f$. Nonuniformities in triangle shape and size were repaired by our remeshing routine (Sec. 6) followed by projection back onto the surface $f$. Using the resulting discrete surface $f_h$ we computed the Barnes-Hut energy $E_h(f_h)$ (Eq. 17) for varying...
error relative to true energy vs. h, θ

\[ |1 - \varepsilon_{h,\theta}/\varepsilon| \]

error relative to discrete energy vs. θ

\[ |1 - \varepsilon_{h,\theta}/\varepsilon_h| \]

Fig. 10. Empirically, our discrete tangent-point energy appears to converge to the true smooth energy at a rate somewhere between \(O(h)\) and \(O(h^2)\), as expected, our Barnes-Hut approximation also converges to the discrete energy as \(\theta \to 0\). Reference values are obtained by applying highly accurate numerical integration to the tangent-point energy on a smooth parameterized surface (triangulated in top right). See supplemental for additional examples.

8.2.1 Comparison Methods. Our comparisons are guided by the extensive comparisons from Yu et al. [2021, Section 7]; we compare with the best of those methods. As a baseline we consider ordinary \(L^2\) gradient descent, which replaces \(A\) in Eq. 14 with the mass matrix. Likewise, replacing \(A\) with the weak Laplacian \(\Delta\) (encoded by the cotan matrix) yields standard \(H^1\) Sobolev preconditioning; \(H^2\) Sobolev preconditioning is achieved by solving Eq. 14 with the weak bi-Laplacian \(\Delta^2\) in place of \(A\). (This latter preconditioner is essentially an ideal choice for Willmore flow [Schumacher 2017].) Like \(H^1\) preconditioning, the accelerated quadratic proxy (AQP) method uses the weak Laplacian \(\Delta\) as the inner product, but also computes a Nesterov acceleration step from the previous two configurations; this strategy is compatible only with linear constraints [Kovalsky et al. 2016, Section 2]. Another common strategy, which we refer to as \(H^2\) L-BFGS, is to initialize L-BFGS with the weak Laplacian rather than the identity matrix, and likewise use the Laplacian to evaluate inner products. Finally, Blended cured quasi-Newton (BCQN) essentially interpolates between ordinary \(H^1\) Sobolev preconditioning and \(H^2\) L-BFGS, and uses barrier penalties to prevent triangle inversion. Since our flow is almost \(H^2\) orthogonal with tangential motions (and since we remesh) we do not experience inversions, and hence omit inversion barriers/inversion-aware line search.

8.3 Time Step Restriction

Fig. 5 verifies that matching the order of the inner product to that of the energy differential essentially lifts the mesh-dependent time step restriction. Here, we sampled the same surface at three resolutions, and ran each method for the same number of iterations. Our \(H^s\) scheme makes more progress for an equal number of iterations—but more importantly, the per-iteration progress of \(H^s\) is largely unaffected by mesh resolution, whereas all other methods slow down as resolution increases. Hence, even if some of these methods could be further accelerated by a constant factor (e.g., via code-level optimization), asymptotic behavior would ultimately dominate.

8.4 Wall-Clock Performance

We timed real-world performance of each method on several challenge meshes, using an AMD Ryzen Threadripper 3990X with 32 GB of RAM. Though our solver benefits from multiple threads (see Sec. 1), we ran this benchmark single-threaded to ensure fair comparison. Fig. 12 plots energy as a function of time; we ran each method...
Fig. 11. Gallery of isotopies obtained by minimizing tangent-point energy—notice that highly knotted surfaces, as well as surfaces with thin sheets and handles, successfully flow to their canonical embeddings. Surfaces are grouped by their isotopy equivalence classes, which are extremely difficult to determine via visual inspection (and also not simply determined by Euler characteristic—see Fig. 16). Labeled meshes are used for performance comparisons in Fig. 12.

Fig. 12. Energy plots showing the effectiveness of a suite of methods at minimizing the tangent-point energy. Our $H^s$ method (in green) reaches minimizers more quickly and consistently than the alternatives. Iterations where energy blows up (above $10^{10}$) causing the AQP method to fail are marked with an X. Renderings of the meshes used and their minimizers can be seen in Fig. 11.

Fig. 13. Per-step timings for a representative set of examples—notice scaling is roughly linear with mesh size.

9 EXAMPLES AND APPLICATIONS

We here explore a variety of applications that help to further evaluate our method, show how it can be used in context, and also identify issues that might be improved in future work. These applications are also illustrated in the accompanying video—note that for many of these examples we take time steps far smaller than the optimal step determined by line search, in order to produce smooth animation.
input surface (genus g)

Fig. 14. Top: even careful illustrations of topological phenomena (here drawn by mathematician Peter Lynch) can be difficult to understand without a good visual imagination. Bottom: our method automatically generates continuous motions that are easier to interpret (see video), enabling exploration by students and researchers who do not have significant artistic training.

9.1 Mathematical Visualization and Exploration

A basic question in geometric topology is whether two embedded manifolds are the same up to *ambient isotopy*—intuitively, whether one surface can be deformed into another by smoothly warping the space around it. More formally, an ambient isotopy between two embeddings \( f_0, f_1 : M \to \mathbb{R}^3 \) is a continuous map \( F : \mathbb{R}^3 \times [0, 1] \to \mathbb{R}^3 \) such that for all \( x \in M, F(x, 0) = x, F(f_0(x), 1) = f_1(x), \) and \( F(x, t) \) is a homeomorphism from \( \mathbb{R}^3 \) to \( \mathbb{R}^3 \) for every time \( 0 \leq t \leq 1 \).

In general this equivalence question can be quite hard to answer—for instance, even detecting whether a given embedding of the circle in \( \mathbb{R}^3 \) is equivalent to the unit circle (or “unknot”) has not yet admitted a polynomial time algorithm [Lackenby 2016]. Hence, computational tools are used to explore such questions experimentally; a notable example for curves is KnotPlot [Scharin 1998]. The software developed for our project effectively provides the first “KnotPlot for surfaces.” Especially the fact that our solver exhibits rapid convergence and excellent scaling enables us to investigate questions that would be impossible with naive numerical methods.

9.1.1 Canonical Embeddings. Global minimizers of geometric energies provide the “simplest” possible geometric representative of a given topological space. Such minimizers also play a critical role in geometric algorithms since they provide a canonical domain for, e.g., surface correspondence and data transfer—see for instance recent algorithms in both the intrinsic [Schmidt et al. 2020; Gillespie et al. 2021] and extrinsic [Kazhdan et al. 2012; Ye et al. 2018] settings. Formally proving that a given surface is a global minimizer is quite challenging. For instance, even the classic Willmore conjecture (which says that the Clifford torus minimizes Willmore energy for genus-1 surfaces) was resolved only very recently, after about 50 years of sustained effort [Marques and Neves 2014]. Hence, numerical tools are essential for formulating hypotheses about the behavior of minimizers and other critical points. To date, there are no clear conjectures about tangent-point minimizers for surfaces of genus \( g \geq 2 \). For reasons discussed in Sec. 1, these minimizers likely exhibit symmetries in \( \mathbb{R}^3 \) rather than \( S^3 \), making them potentially useful as a base domain for algorithms in extrinsic shape processing. To do so, one would simply need to track the parametric correspondence (e.g., via UV-coordinates), and perhaps minimize tangential distortion after flowing to a geometric minimizer (à la Schmidt et al. [2020]).
Fig. 16. Geometric functionals provide a bridge between topology and geometry by enabling one to construct canonical geometric representatives of a given topological space. Here, minimizers of tangent point energy are used to visualize nontrivial isotopy classes of a genus-2 surface. (Numbers indicate number of crossings; subscripts index trivalent graphs from [Ishii et al. 2012, Table 1]).

Fig. 17. Top: minimizers of tangent-point energy often exhibit three-dimensional symmetries which can be difficult to understand from a single view—by adding an attracting plane, we get embeddings that can be nicely displayed in two-dimensional illustrations. Bottom: constrained minimizers for genus 2 through 6.

graph from [Ishii et al. 2012, Table 1], and construct a topologically equivalent initial mesh that is optimized by our approach (see inset). As with knots most of these minimizers do not exhibit much extrinsic symmetry, except for, e.g., 67 and 53 which exhibit bilateral and 3-fold symmetry, resp.

Planar Representatives. Although minimizers exhibit a high degree of symmetry in \( \mathbb{R}^3 \), it can be hard to determine even the genus of a minimizer when viewed from just a single viewpoint. In contrast, topological figures depicted by expert illustrators tend to be somewhat “2.5-dimensional” so that they can be better understood when projected onto the image plane. We can replicate this behavior by adding a simple attractive plane potential, as depicted in Fig. 17, yielding minimizers that are much easier to recognize (contrast with Fig. 15). An additional plane constraint yields a linear arrangement of handles, as commonly drawn by hand (see inset).

9.1.2 Illustrating Isotopies. Our method also provides significant utility for mathematical visualization and illustration. Traditionally, interesting homotopies and isotopies are depicted by a sequence of drawings (or perhaps physical models) highlighting key moments of transition—a practice that has developed over time into a true art form [Francis and Francis 1987]. However, even the best drawings can be difficult to understand without significant thought and visual imagination. To obtain continuous motions (that are more easily understood), a small number of carefully “hand-crafted” computer animations have been produced over the years by either artist keyframing, or explicit programming of meticulously derived parametric formulas [Levy and Thurston 1995; Bednorz and Bednorz 2019]. More recently, automatic optimization-based tools have been used to produce animations, such as the minimax sphere eversion [Francis et al. 1997], as well as recent work in computer graphics on metric embedding [Chern et al. 2018] and conformally-constrained Willmore surfaces [Soliman et al. 2021]. Since these optimization-based tools are largely automatic, they help to democratize the creation of topological animations—our scheme extends such tools to the important and difficult case of ambient isotopies.

Fig. 18. Surprisingly, one can remove a handle of a double torus from a loop or pole without cutting or pinching the surface. Top: hand-drawn illustration by Wells [1997]. Bottom: isotopy computed automatically by our method (see video); no keyframing or boundary conditions were used.

the repulsive strength of the cylinder near the end of the animation,

better depicted in the accompanying video. To create this animation

we simply minimize tangent-point energy from both start and end

configurations, together with a potential that encourages the surface
to lay parallel to the view plane. Since we reach the same minimizer

in both cases (seen in Fig. 1, far right), we can compose these two

sequences (one in reverse) to depict the complete motion. Other

similar examples are shown in Fig. 11, and in the video.

Fig. 18 shows another classic example: removing one handle of a

pair of handcuffs from a rigid pole or ring. The hand-drawn illus-

tration helps to indicate several stages of this isotopy, which are

also captured in our animation. However, the remarkable fact about

our version is that it is driven purely by energy minimization—we

did not perform any keyframing, nor impose any boundary condi-
tions, yet it still constructs an isotopy in several "stages": flatten

out the two handles, perform a so-called IH-

move (see Fig. 19 and [Ishii 2008]), and then

optimize the geometry of the untangled sur-

face. Our specific setup here is to minimize
tangent-point energy while fixing surface area,

and incorporating an infinite repulsive cylin-
der (modeled by an implicit surface). As in the previous example

we use an attractive plane orthogonal to the pole to obtain a more

canonical-looking minimizer. The only hand-tuning was reducing

the repulsive strength of the cylinder near the end of the animation,
to give the handles of the final surface a similar size. Importantly,

allowing the barycenter to float freely (à la Sec. 7.1.1) is essential

here, since the center of mass must ultimately move away from the

pole.

Punctured Torus Eversion. Our discrete tangent-point energy can

also be evaluated on surfaces with boundary, since we simply take

a sum over pairs of triangles. Since we did not develop a careful
treatment of boundary conditions, we simply penalize the total

length and total squared curvature to ensure the boundary at least

remains regular. In Fig. 20 we use this setup to compute an isotopic
eversion between the two orientations of a punctured torus. Un-

like the classical sphere eversion, where one typically starts with

a symmetric midsurface and flows toward the round sphere, we

start with the punctured torus and use our flow to find the mid-
surface. The key observation is that the oriented volume of the

surface \( \int_M \langle f(x), N_f(x) \rangle \, dx_f \) will be zero for a symmetric configu-

ration; fixing the area ensures that our zero-volume penalty does not

cause the surface to collapse to a point. Once we reach zero volume

we transform the midsurface by a reflection and 90-degree rotation,

and run the same flow in reverse (with opposite colors) to obtain

the eversion.

9.2 Geometry Processing and Shape Modeling

The no-collision condition is also natural in geometry processing and shape modeling, especially when a surface is meant to repre-
sent the boundary of a solid object (e.g., for computational fabrication). Tangent-point energy can be used to augment existing geo-

defometric modeling and processing tasks with short- and long-range collision avoidance—

we here explore several aspirational examples.

In general, there has been relatively lit-
tle work on collision-aware geometric mod-
eling. For instance, Harmon et al. [2011]

and Fang et al. [2021] explore modeling sys-
tems based on local collision penalties [Li

et al. 2020], similar in spirit to classic log

barrier methods [Boyd et al. 2004, Section

11.2]. However, since these penalties do not
discretize a smooth energy, their behavior will depend on surface tes-
sellation; moreover, descent strategies developed for these methods

are tailored to local collisions, rather than long-range interactions

and global untangling (à la Sec. 9.1). Other methods explicitly mesh

the free space between objects [Müller et al. 2015; Jiang et al. 2017],

which is costly for 3D problems, and cumbersome for problems with

large deformations.

Proximity-Aware Variational Modeling. As a basic example, Fig. 21

does a simple example of interactive surface editing, where surface

geometry is guided by point constraints, and nearby geometry is

moved out of the way by the tangent-point energy. To better pre-
serve the details of an initial mesh one might also combine tangent-

point energy with a discrete shell energy [Grinspun et al. 2003],

which would entail transferring the material configuration across

meshing operations (a question which is beyond the scope of this

work). Fig. 22 shows another example where pinned points and

edges are interpolated while optimizing the rest of the geometry.

(Here we disable remeshing, but could easily modify remeshing to

ignore pinned vertices). Unlike harmonic interpolation or area min-
imization, for which point constraints are ill-posed, we get nice cur-

vature behavior even near the pins; unlike Willmore flow (which pro-

vides good curvature behavior), we avoid self-intersection. Tangent-

point energy could also in principle be used as a regularizer to
discourage collision in other common modeling paradigms, such as

as rigid as possible (ARAP) modeling [Sorkine and Alexa 2007].

Fig. 19. An IH-move.

Fig. 21. Modeling with long-range influence.
increase volume (no pins)
increase volume (dense pins)
constant area (sparse pins)

Fig. 22. The tangent-point energy can be used to make variational surface modeling responsive to proximity, rather than just collisions. Here for instance we pin a sparse or dense set of points and modify volume and surface area to adjust the appearance of some text (in some cases enclosed in a box). Like Willmore energy (top right), we get smooth behavior near point constraints (see magnified portion), but avoid overlap.

Fig. 23. Here we perform a simple “shrink wrapping” to obtain a manifold, intersection-free reconstruction (top), which works well even for points or polygon soup with severe holes and missing data.

9.2.1 Shrink Wrapping. One class of methods for reconstructing a surface from a collection of points is to “shrink-wrap” them with a triangle mesh [Kobbelt et al. 1999; Hanocka et al. 2020]; such methods are especially suitable in problems where one wishes to fit a high-quality template mesh to a known class of shapes (e.g., head or body scans). A basic problem, however, is that the mesh can get “tangled” during wrapping, inhibiting progress or requiring intricate remeshing to resolve self-intersections. Tangent-point energy may prove useful as a regularizer for such methods—Fig. 23 shows a basic shrink wrapping example on a point cloud, and on a polygon soup with severe holes. Here we minimize tangent-point energy with a gradually decreasing volume constraint.

9.2.2 Nested Envelopes. In a similar vein, nested sequences of solids $U_1 \subset \cdots \subset U_k \subset \mathbb{R}^n$ represented by progressively coarser meshes have applications in multiresolution solvers, cage-based editing, and physical simulation [Sacht et al. 2015]. In Fig. 24 we construct each surface $\partial U_k$ by minimizing tangent point energy plus a volume constraint, and gradually adjusting the constrained volume to achieve a fixed constant factor (here, 1.15x) of the volume of $\partial U_{k-1}$. This variational approach may offer interesting generalizations of ordinary nested cages, since it can easily incorporate constraints and objectives beyond just collision avoidance.

9.2.3 Generative Modeling. Rather than using the tangent-point energy to edit or process existing data, we can also use it to generate new geometry. In nature, the growth of organic shapes is often governed by simple combinations of objectives, e.g., a balance between area and volume while avoiding self-collision. We can likewise use such forces to drive the growth of organic-looking objects, such as the “walnut” depicted in Fig. 25, top. The same technique is used in
9.2.4 Resolving Intersections. In many geometry processing tasks, input data is not free of self-intersections. For exponents $p > 4$, the tangent-point energy $\mathcal{E}_P$ of a non-embedded surface is infinite; to resolve intersections in the input, we can try reducing the exponent to a value $p < 4$, at which point $\mathcal{E}_P$ becomes finite but still discourages collision. Here we find that it also helps to disable the low-order term from Eq. 8. Empirically, the same system framework now appears capable of eliminating small self-intersections (Fig. 26, top), though struggles in more difficult scenarios like the Klein bottle depicted in Fig. 26, bottom, which cannot be globally embedded without self-intersection. Further analysis of the energy for these “subcritical” values may help to provide more robust tools for global collision resolution.

10 LIMITATIONS AND FUTURE WORK

The experiments from Sec. 9 suggest many opportunities for improvement. For instance, major performance gains could be achieved purely through better software engineering, e.g., better parallel implementation of hierarchical matrix multiplication (which is currently bottlenecked around 4–8 threads), or curvature-adapted remeshing (à la [Dunyach et al. 2013]) to reduce mesh size. It would also be useful to track attributes across remeshing operations, to enable (for instance) mapping of data from one shape to another through the canonical minimizer. Since we discretize the tangent-point energy, we provide no hard guarantee that collisions will not occur (Fig. 27). One pragmatic solution is to simply perform continuous collision detection to limit the time step, as done for many years in computer animation [Moore and Wilhelms 1988] and knot drawing [Scharein 1998] (and more recently in geometry processing [Smith and Schaefer 2015; Jiang et al. 2017; Li et al. 2020]). Better might be to approximate tangent-point energy via a hard upper bound on each element pair, akin to the MD energy in Scharein [1998, Section 3.5.1], or element-element penalties from Li et al. [2020].

Several issues require deeper investigation. For one, unlike Yu et al. [2021], our preconditioner cannot accommodate dense constraints (e.g., preservation of each triangle area), which would require $O(|F|)$ iterative solves. Here one can instead use a stiff penalty; revisiting the multigrid approach via hierarchical coarsening [Botsch and Kobbelt 2004; Shi et al. 2006] may also prove fruitful. Our energy approximation becomes inaccurate in situations of very tight contact (à la Sections 9.2.1 and 9.2.2), since we have few quadrature points per unit surface area; adding additional quadrature points (or adaptive refinement) in regions of near-contact may yield tighter fits. A related issue is that some amount of bending regularization is inherent in the energy itself, making it hard to approximate, e.g., sharp edges.

For shape interpolation and mathematical visualization, it would be quite useful to find trajectories that minimize total tangent-point energy (over time), rather than just flowing to a common minimizer—a work on shell-space geodesics may prove valuable [Heeren et al. 2012]. Likewise, integrating repulsive regularization into a thin shell model may help retain a “memory” of the initial shape. Finally, we do not treat Neumann boundary conditions, nor more general arrangements of repulsive curves and surfaces that may have interesting modeling applications.

A ACTION OF THE FRACTIONAL OPERATORS

In section Sec. 5.1 we claimed that the actions of the fractional operators $L^\sigma$, $B$, and $B_0$ can be expressed by suitable kernel matrices that we then compress by hierarchical methods. This is not obvious, so we include a brief derivation here. Consider the kernel matrix

$$H_{ST} := (1 - \delta_{ST})|X_f(S) - X_f(T)|^{-(2\sigma + 2)}.$$ 

Rewriting Eq. 11 for general $u$ and $v \in \mathbb{R}^{[V]}$ in terms of this kernel yields

$$u^T L^\sigma v = \sum_{S \in F} \sum_{T \in F} (\bar{u}(S) - \bar{u}(T)) (\bar{v}(S) - \bar{v}(T)) a_f(S) H_{ST} a_f(T).$$

Multiplying the product inside the sum gives

$$(\bar{u}(S) \bar{v}(T) - \bar{u}(T) \bar{v}(S)) a_f(S) H_{ST} a_f(T)$$

for the pair $(S, T)$. Because $H_{ST} = H_{TS}$, we can move some terms between the summands for $(S, T)$ and $(T, S)$, and then reorganize the sum into

$$u^T L^\sigma v = 2 \sum_{S \in F} \sum_{T \in F} \left( \bar{u}(S) \bar{v}(T) - \bar{u}(T) \bar{v}(S) \right) a_f(S) H_{ST} a_f(T)$$

$$= 2 \sum_{S \in F} \bar{u}(S) a_f(S) \left( \left| a_f(S) \right|^{-1} \sum_{T \in F} H_{ST} a_f(T) \right) a_f(T) \bar{v}(S) - 2 \sum_{S \in F} \sum_{T \in F} \bar{u}(S) a_f(S) H_{ST} a_f(T) \bar{v}(T).$$

Recall that $U \in \text{Hom}(\mathbb{R}^{[V]}, \mathbb{R}^{[F]})$ is defined by $(Uu)(S) = a_f(S) \bar{u}(S)$. Thus the above collapses to

$$u^T L^\sigma v = 2 u^T U^T \text{diag}(a_f) \text{diag}(H a_f) U v - 2 u^T U^T H U v$$

$$= 2 u^T U^T \left( \text{diag} \left( \text{diag}(a_f)^{-1} H a_f \right) - H \right) U v.$$ 

The derivation follows analogously for the high- and low-order matrices $B$ and $B_0$, with the substitution of the operator $V = \text{diag}(a_f) D_f$ for $U$ in the case of $B$.

B FAST MATRIX-VECTOR MULTIPLICATION

Step 1 of Sec. 5.1.5 corresponds to thinning out the matrix shown in Fig. 6 by removing all the green parts. The remainder is a sparse block matrix with variable block size. We store this sparse matrix in CSR format and evaluate products using sparse BLAS routines.

In Step 2 the kernel matrix $H_{IJ} X_f$ is compressed into the rank-one-matrix $I_f h(X_f, P_f; X_{Jf}, P_{Jf}) 1_f^T$. In this step, we are cautious not to move the input data $X_f$ and output data $y_f$ directly to and from the clusters $I$ and $J_f$. Instead, as is common for multipole methods, we store data on BVH clusters. For each cluster $I$, $J_f$, we allocate scalars $x_f$ and $y_f$. Starting with leaf clusters, we set

$$\hat{x}_f := \sum_{T \in I} x(T)$$

for each leaf cluster $J_f$. Then, during a parallel traversal of the BVH in post-order, for each cluster $J_f$, we add the $x$-values of its children into $\hat{x}_f$. After this upward pass is finished, we loop over all clusters $I$ and set

$$\bar{y}_f := \sum_{J_f} h(X_f, \bar{P}_f; X_{Jf}, P_{Jf}) \hat{x}_f.$$ 

with the sum over all $J_f$ such that $(I, J_f)$ is admissible. This can be evaluated via sparse matrix multiplication: first, we fix an ordering of the BVH clusters, e.g., depth-first ordering. Then we assemble a sparse matrix $\hat{H}$ with the nonzero value $h(X_f, \bar{P}_f; X_{Jf}, P_{Jf})$ at the position that correspond to the admissible block cluster $(I, J_f)$. Storing $\hat{x}$ and $\bar{y}$ as vectors, Eq. 22 amounts to

$$\bar{y} \leftarrow \hat{H} \hat{x}.$$ 

Afterwards, we use a downward pass through the BVH to distribute the $\bar{y}$-values back into the vector $y$. We traverse the BVH in pre-order and let each cluster $I$ adds its $\bar{y}$-value into each of its children’s $\bar{y}$-values. Finally each leaf cluster adds its value into each of its member’s $y$-entry, i.e.,

$$y(S) \leftarrow y(S) + \bar{y}_I$$

for each leaf $I$ and each $S \in I$.

The structure of the kernel matrices of $L^\sigma$, $B$, and $B_0$ is very similar. This allows us to use a single block cluster tree to compress all of them. Moreover, the sparsity patterns for the two sparse matrices used to perform Steps 1 and 2 can be shared and the corresponding nonzero values can be computed in a single parallelized loop over the admissible and inadmissible blocks, resp.

For the application of $A_3$ to a vector $v$ of size $3|V|$, we could apply $A = B + B_0$ separately on three vectors $v_1$, $v_2$, and $v_3$ of size $|V|$ that each store only one spatial component of the vertex positions. However, it turns out to be more efficient to store $v_1$, $v_2$, and $v_3$ as columns of a matrix of size $|V| \times 3$ and to replace the sparse matrix-vector products by sparse matrix-dense matrix products.
