

The Convergence of Bird Flocking ^{*}

BERNARD CHAZELLE [†]

Abstract

We bound the time it takes for a group of birds to reach steady state in a standard flocking model. We prove that (i) within single exponential time fragmentation ceases and each bird settles on a fixed flying direction; (ii) the flocking network converges only after a number of steps that is an iterated exponential of height logarithmic in the number of birds. We also prove the highly surprising result that this bound is optimal. The model directs the birds to adjust their velocities repeatedly by averaging them with their neighbors within a fixed radius. The model is deterministic, but we show that it can tolerate a reasonable amount of stochastic or even adversarial noise. Our methods are highly general and we speculate that the results extend to a wider class of models based on undirected flocking networks, whether defined metrically or topologically. This work introduces new techniques of broader interest, including the *flight net*, the *iterated spectral shift*, and a certain *residue-clearing* argument in circuit complexity.

1 Introduction

What do migrating geese, flocking cranes, bait balls of fish, prey-predator systems, and synchronously flashing fireflies have in common? All of them are instances of *natural algorithms*, ie, algorithms designed by evolution over millions of years. By and large, their study has been the purview of dynamical systems theory within the fields of zoology, ecology, evolutionary biology, etc. The main purpose of this work is to show how combinatorial and algorithmic tools from computer science might be of benefit to the study of natural algorithms—in particular, in the context of collective animal behavior [20]. We consider a classical open question in bird flocking: bounding the convergence time in a standard neighbor-based

^{*}A preliminary version of this work appeared in *Proceedings of ACM-SIAM Symposium on Discrete Algorithms (SODA09)*, January 4–6, 2009, 422–431. model. We give a tight bound on the number of discrete steps required for a group of n birds to reach steady state. We prove that, within time exponential in n , fragmentation ceases and each bird settles on a fixed flying direction. We also show that the flocking network converges after a number of steps that never exceeds an iterated exponential of height logarithmic in n . Furthermore, we show that this exotic bound is in fact optimal. If we view the set of birds as a distributed computing system, our work establishes a tight bound on the maximum execution time. Holding for a large family of flocking mechanisms, it should be thought of as a *busy beaver* type result—or perhaps *busy goose*.

The bound is obtained by investigating an intriguing “spectral shift” process, which could be of independent interest. In the model, birds forever adjust their velocities at discrete time steps by averaging them with their neighbors flying within a fixed distance. The model is deterministic but we show that it tolerates a reasonable amount of stochastic or even adversarial noise. While, for concreteness, we settle on a specific geometric model, our methods are quite general and we suspect the results can be extended to a large class of flocking models, including topological networks [1]. The only serious limitation is that the flocking network must be undirected: this rules out models where one bird can process information from another one while flying in its “blind spot.”

Bird flocking has received considerable attention in the scientific and engineering literature, including the now-classical *Boids* model of Reynolds [21, 26–28]. Close scrutiny has been given to leaderless models where birds update their velocities by averaging them out over their nearest neighbors. Two other rules are often added: one to prevent birds from colliding; the other to keep them together. Velocity averaging is the most general and fundamental rule and, understandably, has received the most attention. Computer simulations support the intuitive belief that, by repeated averaging, each bird should eventually converge to a fixed speed and heading. This has been proven theoretically, but how long it takes for the system to converge had remained an open problem. The existential question (does the system converge?) has been settled in many different ways, and it is useful to review the history briefly.

A “recurrent connectivity” assumption stipulates that, over any time interval of a fixed length, every pair of birds should be able to communicate with each other, directly or indirectly via other birds. Jadbabaie, Lin, and Morse [9] proved the first of several convergence results under that assumption (or related ones [16, 17, 23, 27]). Several authors extended these results to variable-length intervals [8, 13, 15]. They established that the bird group always ends up as a collection of separate flocks (perhaps only one), each one converging toward its own speed and heading. Some authors have shown how to do away with the recurrent connectivity assumption by changing the model suitably. Tahbaz-Salehi and Jadbabaie [24], for example, assume that the birds fly on the surface of a torus. Cucker and Smale [7] use a broadcast model that extends a bird’s influence to the entire group while scaling it down as a function of distance. In a similar vein, Ji and Egerstedt [10] introduce a hysteresis rule to ensure that connectivity increases over time. Tang

and Guo [25] prove convergence in a high-density probabilistic model. Recent work [1] suggests a “topological” rule for linking birds: a bird is influenced by a fixed number of its neighbors instead of all neighbors within a fixed distance. Whether the criteria are metric or topological, the bulk of work on leaderless flocking has assumed neighbor-based consensus rules. We are not aware of any bounds on the convergence time.

Our model is a variant of the one proposed by Cucker and Smale [7], which is itself a holonomic variant of the classical Vicsek model [29]. Given n birds $\mathcal{B}_1, \dots, \mathcal{B}_n$, represented at time t by points $x_1(t), \dots, x_n(t)$ in E^3 , the *flocking network* G_t has a vertex for each bird and an edge between any two of them within distance 1 of each other. By convention, G_t has no self-loops. The connected components of G_t are the *flocks* of the system. If $d_i(t)$ denotes the number of birds adjacent to \mathcal{B}_i at time t , the total number of birds within the closed unit disk centered at \mathcal{B}_i is precisely $d_i(t) + 1$.

Figure 1: Each bird updates its velocity by averaging it with those of its neighbors within a unit-radius circle.

The Model. The input consists of the initial position $x(0)$ and velocity $v(1)$. Both vectors belong to \mathbb{R}^{dn} , for any fixed $d \geq 1$. For $t \geq 1$ and $1 \leq i \leq n$,

$$x_i(t) = x_i(t-1) + v_i(t),$$

where¹

$$v_i(t+1) - v_i(t) = c_i(t) \sum_{(i,j) \in G_t} (v_j(t) - v_i(t)).$$

¹ We denote the coordinates of a vector $x(t)$ by $x_i(t)$ and the elements of a matrix $X(t)$ (resp. X_t) by $x_{ij}(t)$ (resp. $(X_t)_{ij}$).

The *self-confidence* coefficients $c_i(t)$, so named because they tell us how much a bird is influenced by its neighbors, are normalized so that $0 < c_i(t)d_i(t) < 1$. (See “Discussion” section below for an intriguing interpretation of these constraints.) We assume that $c_i(t)$ may vary only when G_t does; in other words, while all neighborly relations remain the same, so do the self-confidence coefficients. A natural choice of coefficients is the one used in the classical Vicsek model [29]: $c_i(t) = (d_i(t) + 1)^{-1}$, but we do not make this restrictive assumption here.

The model captures the simple intuition that, in an effort to reach consensus by local means, each bird should adjust its velocity at each step so as to be a weighted average of those of its neighbors. A mechanical interpretation sees in the difference $v_i(t+1) - v_i(t)$ the discrete analogue of the bird’s acceleration, so that, by Newton’s Law, $F = ma$, a bird is subject to a force that grows in proportion to the differences with its neighbors. A more useful take on the model is to view it as a diffusion process: more precisely, as the discrete version of the heat equation

$$\frac{\partial v}{\partial t} = -C_t L_t v,$$

where the Laplacian L_t of the flocking network G_t is defined by:

$$(L_t)_{ij} = \begin{cases} d_i(t) & \text{if } i = j; \\ -1 & \text{if } (i, j) \in G_t; \\ 0 & \text{else.} \end{cases}$$

and $C_t = \text{diag } c(t)$ is the self-confidence matrix. Thus we express the dynamics of the system as

$$v(t+1) - v(t) = -C_t L_t v(t).$$

This is correct in one dimension. To deal with birds in d -space, we use a standard tensor lift. Here is how we do it. We form the velocity vector $v(t)$ by stacking $v_1(t), \dots, v_n(t)$ together into one big column vector of dimension dn . Given a matrix A , the product² $(A \otimes I_d)v(t)$ interlaces into one vector the d vectors obtained by multiplying A by the vector formed by the k -th coordinate of each $v_i(t)$, for $k = 1, \dots, d$. The heat equation would now be written as

$$v(t+1) = (P(t) \otimes I_d)v(t).$$

where $P(t) = I_n - C_t L_t$. One can check directly that the *transition matrix* $P(t)$ is row-stochastic. In the case of a 3-node path, for example, $P(t)$ has the form:

$$\begin{pmatrix} 1 - c_1(t) & c_1(t) & 0 \\ c_2(t) & 1 - 2c_2(t) & c_2(t) \\ 0 & c_3(t) & 1 - c_3(t) \end{pmatrix}.$$

² The Kronecker $A \otimes B$, product of two matrices A and B is the matrix we get if we replace each a_{ij} by the block $a_{ij}B$. Formally, if A is m -by- n and B is p -by- q , then the product $A \otimes B$ is the mp -by- nq matrix C such that $c_{ip+j, kq+l} = a_{i,k}b_{j,l}$. We will often use, with no further mention, the tensor identity $(A \otimes B)(C \otimes D) = AC \otimes BD$.

Figure 2: A 3-node flock with the transitions of the middle node indicated by curved arrows.

The dynamics of flocking is captured by the two equations of motion: For any $t \geq 1$,

$$\begin{cases} x(t) = x(t-1) + v(t); \\ v(t+1) = (P(t) \otimes I_d)v(t). \end{cases} \quad (1)$$

For tie-breaking purposes, we inject a tiny amount of hysteresis into the system. As we discuss below, this is necessary for convergence. Intuitively, the rule prevents edges of the flocking network from breaking because of microscopic changes. Formally, an edge (i, j) of G_t remains in G_{t+1} if the distance between \mathcal{B}_i and \mathcal{B}_j changes by less than $\varepsilon_h > 0$ between times t and $t+1$. We choose ε_h to be exponentially small for illustrative purposes only; in fact, virtually *any* hysteresis rule would work.

The Results. To express our main result, we need to define the fourth level of the Ackermann hierarchy, the so-called “tower-of-twos” function: $2 \uparrow\uparrow 1 = 2$ and, for $n > 1$, $2 \uparrow\uparrow n = 2^{2 \uparrow\uparrow (n-1)}$. The bird group is said to have reached *steady state* when its flocking network no longer changes. All the results below hold in any fixed dimension $d \geq 1$.

- *A group of n birds reaches steady state in fewer than $2 \uparrow\uparrow (4 \log n)$ steps. The maximum number of switches in the flocking network of n birds is at most $n^{O(n^3)}$. The limit configuration of each bird \mathcal{B}_i is of the form $a_i + b_i t$, where a_i, b_i are d -dimensional rational vectors. After the fragmentation breakpoint $t_f = n^{O(n^3)}$, network edges can only appear and never vanish.*
- *There exists an initial configuration of n birds that requires more than $2 \uparrow\uparrow \log \frac{n}{2}$ steps before reaching steady state. The lower bound holds both with and without hysteresis.*

Past the fragmentation breakpoint, the direction of each bird is essentially fixed, so $n^{O(n^3)}$ is effectively the bound for *physical* convergence. (Of course, damped local oscillations typically go on forever.) *Combinatorial* convergence is another matter altogether. It might take an extraordinarily long time before

the network stops switching. The tower-of-twos' true height is actually less than $4 \log n$, ie, a little better than stated above: specifically, the factor 4 can be replaced by $(\log x_0)^{-1}$, where x_0 is the unique real root of $x^5 - x^2 - 1$, which is about 3.912.

Figure 3: Flocks cease to lose edges after the fragmentation breakpoint t_f and can only gain new ones. The network reaches steady state after a tower-of-twos of height logarithmic in the number of birds.

- *How many bits?* The self-confidence matrices C_t are rational with $O(\log n)$ bits per entry. The bound on the maximum number of network switches holds even if the inputs are arbitrary real numbers. Obviously, there is no hope of bounding the convergence time if two birds can be initialized to fly almost parallel to each other; therefore bounding the representation size of the input is necessary. The initial position and velocity of each bird are encoded as rationals over \mathfrak{p} bits. Our results hold for virtually any value of \mathfrak{p} . The dependency on \mathfrak{p} begins to show only for $\mathfrak{p} \geq n^3$, so this is what we shall assume when proving the upper bound on the convergence time. Keep in mind that \mathfrak{p} is only an upper bound and the actual number of bits does not need to be this long. In fact, the lower bound requires only $\log n$ bits per bird. All computation is exact. The upper bound³ of $2 \uparrow \uparrow (4 \log n)$ is extremely robust, and holds for essentially any conceivable input bit-size and hysteresis rule.

- *Is the lower bound pathological?* Surprisingly, the answer is no. As we mentioned, initial conditions require only $\mathfrak{p} = O(\log n)$ bits per bird. Our construction ensures that the hysteresis rule never kicks in, so the lower bound holds whether the model includes hysteresis or not. The flocks used for the construction are single paths,

³ Logarithms to the base 2 are written as \log while the natural variety is denoted by \ln . For convenience we assume throughout this paper that n , the number of birds, is large enough. To handle small bird groups, of course, we can always add fictitious birds that never interact with anyone.

and the matrix $P(t)$ corresponds to a lazy random walk with probability $\frac{1}{3}$ of staying in place. The lower bound holds in any dimension $d > 0$. Here are the initial positions and velocities for $d = 1$:

$$\begin{cases} x(0) = \left(0, \frac{2}{3}, 2, \frac{8}{3}, \dots, 2l, 2l + \frac{2}{3}, \dots, n - 2, n - \frac{4}{3}\right)^T; \\ v(1) = \left(\underbrace{n^{-11}, 0, -n^{-11}, 0, n^{-11}, 0, \dots, n^{-11}, 0, -n^{-11}, 0}_n\right)^T. \end{cases}$$

Flocking obeys two symmetries: one translational; the other kinetic (or “relativistic,” as a physicist might say). The absolute positioning of the birds is irrelevant and adding a fixed vector to each bird’s velocity has no effect on flocking. In other words, one cannot infer velocity from observing the evolution of the flocks. Indeed, only differences between velocities are meaningful. This invariance under translation in velocity space implies that slow convergence cannot be caused by forcing birds to slow down. In fact, one can trivially ensure that no bird speed falls below any desired threshold. The lower bound relies on creating small angles, not low speeds. (Thus, in particular, the issue of stalling does not arise.) To simplify the lower bound proof, we allow a small amount of noise into the system. Within the next $n^{O(1)}$ steps following any network switch, the velocity of an m -bird flock may be multiplied by $I_m \otimes \hat{\alpha}$, where $\hat{\alpha}$ is the diagonal matrix with $\alpha = (\alpha_1, \dots, \alpha_d)$ along the diagonal and rational $|\alpha_i| \leq 1$ encoded over $O(\log n)$ -bits. The noise-free case corresponds to $\alpha_i = 1$. The perturbed velocity at time t should not differ from the original one by more than $\delta_t = \frac{\log t}{t} e^{O(n^3)}$ but we allow a number of perturbations as large as $e^{O(n^3)}$. This noise model could be enriched considerably without affecting the convergence bounds, but our choice was guided by simplicity. Note that some restrictions are necessary for convergence; trivially, noise must be bounded past the last switch since two flocks flying parallel to each other could otherwise be forced to merge arbitrarily far into the future. Switching to a noisy model has two benefits: one is a more general result, since the same upper bound on the convergence time holds whether the noise is turned on or off; the other is a simpler lower bound proof. It allows us to keep the initial conditions extremely simple. We use only $\log n$ perturbations and $\delta_t \approx 1/t$, so noise is not germane to the tower-of-twos growth.

- *Why hysteresis?* Network convergence easily implies velocity convergence, but the converse is not true: velocities might reach steady state while the network does not. Indeed, in §3.2, we specify a group of birds that alternates forever between one and two flocks without ever converging. This is an interesting but somewhat peripheral issue that it is best to bypass, as is done in [10], by injecting a minute amount of hysteresis into the system. Whatever one’s rule—and, as we mentioned earlier, almost any rule would work—it must be sound, meaning that any two birds at distance ever so slightly away from 1 should have the correct pairing status.

Note that soundness does not follow immediately from our definition of hysteresis. This will need to be verified. By construction, we know that any two birds within unit distance of each other at time t are always joined by an edge of the flocking network G_t . We will show that, if we set $\varepsilon_h = n^{-bn^3}$ for a large enough constant b , then no two birds at distance greater than $1 + \sqrt{\varepsilon_h}$ are ever adjacent in G_t .

• *How robust are the bounds?* The tower-of-twos bound continues to hold regardless (almost) of which hysteresis rule we adopt and how many input bits we allow. The assumption $\varepsilon_h = n^{-bn^3}$ is introduced for notational convenience; for example, they allow us to express soundness very simply by saying that no birds at distance greater than $1 + \sqrt{\varepsilon_h}$ should ever be joined by an edge of the network. Without the assumptions above, the bounds are more complicated. For the interested reader, here is what happens to the number $N(n)$ of network switches and the fragmentation breakpoint t_f , ie, the time after which flocks can only merge:

$$\begin{cases} N(n) = n^{O(n^3)} (\mathfrak{p} + \log \frac{1}{\varepsilon_h})^{n-1}; \\ t_f = \frac{1}{\varepsilon_h} n^{O(n^3)} 2^{O(\mathfrak{p})} (\mathfrak{p} + \log \frac{1}{\varepsilon_h})^n. \end{cases}$$

Discussion. How relevant are this paper’s results? Why are they technically difficult? We address these two points briefly. Our bounds obviously say nothing about physical birds in the real world. They merely highlight the exotic behavior of the mathematical models. Although we focus on a Cucker-Smale variant, we believe that the bounds hold for a much wider variety of neighbor-based models. We introduce new techniques that are likely to be of further interest. The most promising seems to be the notion of a “virtual bird” flying back in time. We design a structure, the *flight net*, that combines both kinetic and positional information in a way that allows us to use both the geometry and the algebra of the problem at the same time. Perhaps the most intriguing part of this work is the identification of a curious phenomenon, which we call the (iterated) *spectral shift*.

Self-confidence leads to an interesting phenomenon. Too much of it prevents consensus but so does too little. Harmony in a group seems to be helped by a minimum amount of self-confidence among its members. Both extreme selfishness and excessive altruism get in the way of reaching cohesion in the group. Self-confidence provides a retention mechanism necessary for reaching agreement. The coefficient $c_i(t)d_i(t)$ represents how much a bird lets itself influenced by its neighbors. By requiring that it be less than 1, we enforce a certain amount of self-confidence for each bird. This idea is not new and can be found in [8, 14, 15].

Besides noise and hysteresis, our model differs from Cucker-Smale [7] in two other ways. One is that our flocking networks are not complete graphs: they undergo noncontinuous transitions, which create the piecewise linearity of the system. Another difference is that the transition matrices of our model are not symmetric. This greatly limits the usefulness of linear algebra. The reason why might not be

obvious, so here is some quick intuition. Cucker and Smale diagonalize the Laplacian and note that, since only differences are of interest, the vectors might as well be assumed to lie in the space $\mathbf{1}^\perp$. Not only is that space invariant under the Laplacian but it contracts at an exponential rate set by the Fiedler number (the second eigenvalue). From this, a quadratic Lyapunov function quickly emerges, namely the energy $v^T L_t v$ of the system. When the graph is connected, the Fiedler number is bounded away from 0 by an inverse polynomial, so differences between velocities decay to 0 at a rate of $2^{tn^{-c}}$ for some constant $c > 0$.

In the nonsymmetric case (ours), this approach is doomed. If, by chance, all the transition matrices had the same left eigenvectors, then the variance of the time-dependent Markov chain sampled at the (common) stationary distribution would in fact be a valid Lyapunov function, but that assumption is completely unrealistic. In fact, it has been proven [9, 19] that the dynamical systems under consideration do not admit of any suitable quadratic Lyapunov function for $n \geq 8$. Worse, as was shown by Olshevsky and Tsitsiklis [19], there is not even any hope of finding something weaker, such as a nonzero positive semidefinite matrix Λ satisfying, for any allowable transition $v(t) \rightarrow v(t+1)$,

$$\begin{cases} \Lambda \mathbf{1} = 0; \\ v(t+1)^T \Lambda v(t+1) \leq v(t)^T \Lambda v(t). \end{cases}$$

Our transition matrices are diagonalizable, but the right eigenspace for the subdominant eigenvalues is not orthogonal to $\mathbf{1}$ and the maps might not even be globally nonexpansive: for example, the stochastic matrix

$$\frac{1}{15} \begin{pmatrix} 12 & 3 \\ 10 & 5 \end{pmatrix}$$

has the two eigenvalues 1 and 0.133; yet it stretches the unit vector $(1, 0)$ to one of length 1.041. Linear algebra alone seems unable to prove convergence. The rationality of limit configurations is not entirely obvious. In fact, the iterated spectral shift is reminiscent of lacunary-series constructions of transcendental numbers, which is not the most auspicious setting for proving rationality. This work draws from many areas of mathematics and computer science, including Markov chains, nonnegative matrices, algebraic graph theory, elimination theory, combinatorics, harmonic analysis, circuit complexity, computational geometry, and of course linear algebra.

2 A Bird's Eye View of the Proof

To establish a tight bound on the convergence time, we break down the proof into four parts, each one using a distinct set of ideas. We briefly discuss each one in turn. The first step is to bound the number of network switches while ignoring all time considerations. This decoupling allows us to treat the problem

as purely one of information transfer. In one step a bird influences each one of its neighbors by forcing its velocity into the computation of these neighbors' new velocities. This influence propagates to other birds in subsequent steps in a manner we can easily trace by following the appropriate edges along the time-dependent flocking network. Because of self-confidence, each bird influences itself constantly. It follows that once a bird influences another one (directly or indirectly via other birds) it does so forever, even if the two birds find themselves forever confined to distinct connected components. For this reason, influence alone is a concept of limited usefulness. We need another analytical tool: *refreshed* influence. Suppose that, at time t_0 , \mathcal{B}_1 claims influence on \mathcal{B}_2 . As we just observed, this claim will hold for all $t > t_0$. But suppose that we “reboot” the system at time $t_0 + 1$ and declare all influences void. We may now ask if \mathcal{B}_1 will again claim influence on \mathcal{B}_2 at some time $t > t_0$ in the future: in other words, whether a chain of edges will over time transfer information again from \mathcal{B}_1 to \mathcal{B}_2 after t_0 . If yes, we then speak of refreshed influence. Suppose now that \mathcal{B}_1 exerts refreshed influence on \mathcal{B}_2 infinitely often: we call such influence *recurrent*. Although influence is not a symmetric relation, it is an easy exercise to prove that recurrent influence is.

Figure 4: Each bird is influenced by the one pointing to it. If this chain of influence occurs repeatedly (not necessarily with the same set of intermediate birds), a backward sphere of influence centered at the end of the chain will begin to propagate backwards and eventually reach the first bird in the chain.

This appears to be a principle of general interest. If political conversations consist of many two-way communications between pairs of people, with the pairs changing over time, then the only way A can influence B repeatedly is if it is itself influenced by B repeatedly. What makes this fact interesting is that it holds even if A and B never exchange opinions directly with each other and only a single pairwise communication occurs at any given time. Self-confidence plays an important role in this phenomenon. It provides information retention that

prevents agents from being influenced by their own opinions in periodic fashion. In fixed networks, this avoids the classical oscillation issue for random walks in bipartite graphs.

In time-dependent networks, the role of self-confidence is more subtle. To understand it, one must first remember one fundamental difference between *fixed* directed and undirected consensus networks (ie, where at each step, the opinion at each node v is averaged over the opinions linked to by the edges from v). In a fixed directed network, the fraction of an agent’s opinion that is measurable at some other node of the network might be exponentially small in the time elapsed since that opinion was expressed. This cannot happen in undirected networks: any fraction of an opinion is either 0 or bounded from below independently of time. Time-dependent undirected networks, on the other hand, are expressive enough to (essentially) simulate fixed directed ones: time, indeed, can be used to break edge symmetry. The benefits of undirectedness are thus lost, and time-dependent undirected consensus networks can behave much like fixed directed ones—see [5,6] for an application of this principle to interactive proof systems; in particular, they can witness exponential opinion propagation decay. Adding self-confidence magically prevents such decay. The idea would appear to warrant special scrutiny outside of its native habitat of computer science and control theory.

- *How many switches?* Suppose that \mathcal{B}_1 exerts recurrent influence on \mathcal{B}_2 . We show that, at some point, both birds will join a connected component of the flocking network and remain there forever. How many switches can occur before that event? Let V_1 be the set of birds influenced by \mathcal{B}_1 . As soon as everyone in V_1 has been influenced by \mathcal{B}_1 , let’s “reboot” the system and define V_2 to be the new set of birds with refreshed influence from \mathcal{B}_1 . Obviously $V_1 \supseteq V_2$. Repeating this process leads to an infinite nested sequence

$$V_1 \supseteq V_2 \supseteq V_3 \supseteq \dots \supseteq V_\infty,$$

where V_∞ contains at least the two birds \mathcal{B}_1 and \mathcal{B}_2 . Let T_k be the formation time of V_k and let δ_k be the difference in velocity between the two birds at time T_k . We wish we could claim a uniform bound, $\|\delta_k\|_2 < (1 - \varepsilon)\|\delta_{k-1}\|_2$, for some fixed $\varepsilon > 0$ independent of the time difference $T_k - T_{k-1}$. Indeed, this would show that, for k large enough, the two velocities are close enough for the hysteresis rule to kick in and keep the two birds together in the same flock forever. Of course, since the two birds need not be adjacent, this argument should be extended to all pairs of birds in V_∞ . While the inequality $\|\delta_k\|_2 < (1 - \varepsilon)\|\delta_{k-1}\|_2$ is too much to ask for, we show that $\|\delta_k\|_2 \leq \zeta_k$, where $\zeta_k < (1 - \varepsilon)\zeta_{k-1}$. In other words, the velocity difference between \mathcal{B}_1 and \mathcal{B}_2 may not shrink monotonically, but it is bounded by a function that does. The uniformity of the shrinking, which is crucial, depends critically on self-confidence and the retention mechanism it implies. Technically, this translates into a uniform lower bound on the nonzero entries of products of stochastic matrices. This allows us to rescue the previous argument and bound

the value of k such that $V_k = V_\infty$. To bound the number of switches before time T_k , we need to find how many of them can take place between a reboot at T_{j-1} and the formation of V_j . The key observation is that V_j is formed by a growth process of smaller flocks (ie, all of them of size less than n): we can therefore set up a recurrence relation and bound the number of switches inductively.

- *How much time between switches?* Flock behavior between switches is linear, so spectral analysis provides most of the tools we need to bound the inter-switch time. At time t , the number of bits needed to encode the velocity is (roughly) $O(t)$. This means that, in the worst case, two birds can fly either parallel to each other or at an angle at least $e^{-O(t)}$. From this we can infer that, should the birds want to be joined together in the flocking network after time t , this union must happen within a period of $e^{O(t)}$. Things are more complex if the stationary velocities of the two flocks are parallel. We need to use root separation bounds for various extension fields formed by adjoining to the rationals all the relevant eigen-information. Intuitively, the question we must answer is how long one must wait for a system of damped oscillators to cross a given real semi-algebraic set with known parameters. All of these techniques alone can only yield a convergence time bound in the form of a tower-of-twos of height exponential in n . To bring the height down to logarithmic requires two distinct ideas from computational geometry and circuit complexity.

- *How to bring the height down to linear?* So far, we have only used combinatorics, algebraic graph theory, linear algebra, and elimination theory. We use algorithmic ideas from convex geometry to reduce the height to linear. We lift the birds into 4 dimensions (or $d + 1$ in general) by making time into one of the dimensions. We then prove that, after exponential time, birds can only fly almost radially (ie, along a line passing through the origin). This implies that, after a certain time threshold, flocks can only merge and never fragment again. From that point on, reducing the height of the tower-of-twos to linear is easy. Our geometric investigation introduces the key idea of a *virtual bird*. The stochastic transitions have a simple geometric interpretation in terms of new velocities lying in the convex hulls of previous ones. This allows us to build an exponential-size *flight net* consisting of convex structures through which all bird trajectories can be monitored. A useful device is to picture the birds flying back in time with exactly one of them carrying a baton. When a bird is adjacent to another one in a flock, it may choose to pass its baton. The trajectory of the baton is identified as that of a virtual bird. Because of the inherent nondeterminism of the process, we may then ask the question: is there always a virtual bird trajectory that follows a near-straight line? The answer, obviously negative in the case of actual birds, turns out to be yes. This is the benefit of virtuality. This fact has numerous geometric consequences bearing on the angular flight motion of the real birds.

- *How to bring the height down to logarithmic?* It is not so easy to build intuition

for the logarithmic height of the tower-of-twos.⁴ A circuit complexity framework helps to explain the *residue clearing* phenomenon behind it. To get a tower-of-twos requires an iterated *spectral shift*. When two flocks meet, energy must be transferred from the high-frequency range down to the lowest mode in the power spectrum. This process builds a *residue*: informally, think of it, for the purpose of intuition, as residual heat generated by the transfer. This heat needs to be evacuated to make room for further spectral shifts. The required cooling requires free energy in the form of previously created spectral shifts. This leads to an inductive process that limits any causal chain of spectral shifts to logarithmic length. The details are technical, and the best way to build one’s intuition is to digest the lower bound first.

- *How to prove the optimality of the logarithmic height?* The starting configuration is surprisingly simple. The n birds stand on a wire and fly off together at various angles. The initial conditions require only $O(\log n)$ bits per bird. The n birds meet in groups of 2, 4, 8, etc, forming a balanced binary tree. Every “collision” witnesses a spectral shift that creates flying directions that are increasingly parallel; hence the longer waits between collisions. To simplify the calculations, we use the noisy model to flip flocks occasionally in order to reverse their flying directions along the X -axis. This occurs only $\log n$ times and can be fully accounted for by the model we use for the upper bound. Because the flocks are simple paths, we can use harmonic analysis for cyclic groups to help us resolve all questions about their power spectra.

3 The Upper Bound

We begin with a few opening observations in §3.1. We explore both the algebraic and geometric aspects of flocking in §3.2. We establish a crude convergence bound in §3.3, which gives us a glimpse of the spectral shift. An in-depth study of its combinatorial aspects is undertaken in §3.4, from which a tight upper bound follows. We shall always assume that $\mathfrak{p} \geq n^3$. To highlight the robustness of the bounds, we leave both \mathfrak{p} and ε_h as parameters throughout much of our discussion, thus making it easier to calculate convergence times for arbitrary settings. For convenience and clarity, we adopt the default settings below in §3.4 (but not before). One should keep in mind that virtually any assignment of parameters would still produce a tower-of-twos. Let b denote a large enough constant:

$$\text{DEFAULT SETTINGS} \quad \begin{cases} \mathfrak{p} = n^3; \\ \varepsilon_h = n^{-bn^3}. \end{cases} \quad (2)$$

⁴As a personal aside, let me say that I acquired that intuition only after I had established the matching lower bound. For this reason, I recommend reading the lower bound section before the final part of the upper bound proof.

Recall that \mathfrak{p} and ε_h denote, respectively, the input bit-size and the hysteresis parameter. With these settings, the fragmentation breakpoint and the maximum switch count are both $n^{O(n^3)}$.

3.1 Preliminaries

We establish a few useful facts about the growth of the coordinates over time. It is useful to treat coordinates as integers, which we can do by expressing them as fractions sharing the same denominator. For example, the initial positions and velocities can be expressed either as \mathfrak{p} -bit rationals or, more usefully, as $O(\mathfrak{p}n)$ -bit *CD-rationals*, ie, rationals of the form p_i/q , with the common denominator q . We mention some important properties of such representations. We will also introduce some of the combinatorial tools needed to measure ergodicity. The objective is to predict how fast backward products of stochastic matrices tend to rank-one matrices. We treat the general case in this section and investigate the time-invariant case in the next.

Numerical Complexity. The *footprint* of a matrix A is the matrix \underline{A} derived from A by replacing each nonzero entry by 1. For $t \geq s$, we use $P(t, s)$ as shorthand for $P(t)P(t-1)\cdots P(s)$. Note that, in the absence of noise, the fundamental equation (1) can be rewritten as

$$v(t+1) = (P(t, 1) \otimes I_d)v(1).$$

A bird may influence another one over a period of time without the converse being true; in other words, the matrices $P(t, s)$ and $\underline{P}(t, s)$ are in general not symmetric; the exception is $\underline{P}(t)$, which not only is symmetric but has its diagonal full of ones. Because of this last property, $\underline{P}(t, s)$ can never lose any 1 as t grows, or to put it differently the corresponding graph can never lose an edge. Before we get to the structural properties of $P(t, s)$, we need to answer two basic questions: how small can the nonzero entries be and how many bits do we need to represent them? As was shown in [8, 14], nonzero elements of $P(t, s)$ can be bounded uniformly, ie, independently of t . Note that this relies critically on the positivity of the diagonals. Indeed, without the condition $c_i(t)d_i(t) < 1$, we could choose $P(t) = A$ for even t and $P(t) = B$ for odd t , where

$$A = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix} \qquad B = \frac{1}{2} \begin{pmatrix} 0 & 2 & 0 \\ 1 & 0 & 1 \\ 0 & 2 & 0 \end{pmatrix}.$$

For even $t > 0$,

$$P(t, 1) = (AB)^{t/2} = \begin{pmatrix} 2^{-t/2} & 1 - 2^{1-t/2} & 2^{-t/2} \\ 0 & 1 & 0 \\ 0 & 1 & 0 \end{pmatrix}.$$

To understand this process, think of a triangle with a distinguished vertex called the *halver*. Each vertex holds an amount of money. At odd steps, the halver splits its amount in half and passes on each half to its neighbor; the other vertices, meanwhile, pass on their full amount to the halver. The total amount of money in the system remains the same. At the following (even) step, the role of halver is handed to another vertex (which one does not matter); and the process repeats itself. This alternate sequence of halving and relabeling steps produces an exponential decay. If each vertex is prohibited to pass its full amount, however, then money travels while leaving a “trace” behind. As we prove below, exponential decay becomes impossible. This prohibition is the equivalent of the positive self-confidence built into bird flocking.

LEMMA 3.1. *For any $1 \leq s \leq t$, the elements of $P(t, s)$ are CD-rationals over $O((t - s + 1)n \log n)$ bits. The nonzero elements are in $n^{-O(n^2)}$.*

Proof. Each row of $P(t)$ contains rationals with the same $O(\log n)$ -bit denominator, so the matrix $P(t)$ can be written as N^{-1} times an integer matrix, where both N and the matrix elements are encoded over $O(n \log n)$ bits. Each element of $P(t, s)$ is a product of $t - s + 1$ such matrices; hence a matrix with $O((t - s + 1)n \log n)$ -bit integer elements divided by a common $O((t - s + 1)n \log n)$ -bit integer. For the second part of the lemma, we use arguments from [8,14]. Recall that $P(t) = I_n - C_t L_t$, where C_t is a diagonal matrix of positive rationals encoded over $O(\log n)$ bits, so the case $t = s$ is obvious. Let $\rho(t, s)$ be the smallest positive element of $P(t, s)$ and suppose that $t > s$.

We begin with a few words of intuition. Because $P(s, t) = P(t)P(t - 1, s)$, a nonzero entry $p_{ij}(t, s)$ is the expected value of $p_{kj}(t - 1, s)$, for a random k adjacent to i in $\underline{P}(t)$, or, to be more precise, in the graph induced by the nonzero elements of that matrix. If, for all such k , $p_{kj}(t - 1, s) > 0$, then $p_{ij}(t, s)$, being an average of positive numbers, is at least $\rho(t - 1, s)$, and we are done. On the other hand, having some $p_{kj}(t - 1, s)$ equal to 0 means that the edge (k, j) is missing from the “graph” $\underline{P}(t - 1, s)$. If we now consider the 2-edge path formed by (k, i) in $\underline{P}(t)$ and (i, j) in $\underline{P}(t - 1, s)$, we conclude that at least one of (i, j) or (k, j) is a brand-new edge in $\underline{P}(t, s)$. We then use the fact that such events happen rarely.

- Suppose that $p_{kj}(t - 1, s) > 0$ for each i, j, k such that $p_{ij}(t, s)p_{ik}(t) > 0$. Then, for any $p_{ij}(t, s) > 0$, by stochasticity,

$$p_{ij}(t, s) = \sum_k p_{ik}(t)p_{kj}(t - 1, s) \geq \left(\sum_k p_{ik}(t) \right) \rho(t - 1, s) = \rho(t - 1, s).$$

It follows that $\rho(t, s) \geq \rho(t - 1, s)$.

- Assume now that $p_{ij}(t, s)p_{ik}(t) > 0$ and $p_{kj}(t - 1, s) = 0$ for some i, j, k . Since $p_{ij}(t, s)$ is positive, so is $p_{il}(t)p_{lj}(t - 1, s)$ for some l ; hence $p_{ij}(t, s) \geq p_{il}(t)p_{lj}(t - 1, s) \geq \rho(t - 1, s)n^{-O(1)}$. We show that this drop coincides with

the gain of an 1 in $\underline{P}(t, s)$. The footprint of $P(t)$ is symmetric, so $p_{ki}(t) > 0$ and hence

$$p_{kj}(t, s) = \sum_l p_{kl}(t)p_{lj}(t-1, s) \geq p_{ki}(t)p_{ij}(t-1, s) \geq n^{-O(1)}p_{ij}(t-1, s).$$

We distinguish between two cases. If $p_{ij}(t-1, s)$ is positive, then so is $p_{kj}(t, s)$. Since $p_{kj}(t-1, s) = 0$, the matrix $P(t, s)$ has at least one more positive entry than $P(t-1, s)$; recall that no entry can become null as we go from $P(t-1, s)$ to $P(t, s)$. On the other hand, if $p_{ij}(t-1, s) = 0$, our assumption that $p_{ij}(t, s) > 0$ leads us to the same conclusion. In both cases, $P(t, s)$ differs from $P(t-1, s)$ in at least one place: this cannot happen more than n^2 times.

If we fix s then $\rho(t, s) \geq \rho(t-1, s)$ for all but at most n^2 values of t . For the others, as we saw earlier, $p_{ij}(t, s) \geq \rho(t-1, s)n^{-O(1)}$; hence $\rho(t, s) \geq \rho(t-1, s)n^{-O(1)}$. \square

The coordinates of $v(1)$ and $x(0)$ can be expressed as CD-rationals over $O(\mathfrak{p}n)$ bits. By the previous lemma, this implies that, in the noise-free case, for $t > 1$, $v(t) = (P(t-1, 1) \otimes I_d)v(1)$ is a vector with CD-rational coordinates over $O(tn \log n + \mathfrak{p}n)$ bits. The equation of motion (1) yields

$$x(t) = x(0) + \left((P(t-1, 1) + \cdots + P(1, 1) + I_n) \otimes I_d \right) v(1).$$

Note that $P(t-1, 1) = N^{-1}Q$, where Q is an integer matrix with $O(tn \log n)$ -bit integer elements and N is an $O(tn \log n)$ -bit integer. The other matrices are subproducts of $P(t-1, 1) = P(t-1) \cdots P(1)$, so we can also express them in this fashion for the same value of N . It follows that $v(t)$ and $x(t)$ have CD-rational coordinates over $O(tn \log n + \mathfrak{p}n)$ bits. Adding noise makes no difference asymptotically. Indeed, bringing all the coordinates of the scaling vectors α in CD-rational form adds only $O(n \log n)$ bits to the velocities at each step.

LEMMA 3.2. *For any $t \geq 1$, the vectors $v(t)$ and $x(t)$ have CD-rational coordinates over $O(tn \log n + \mathfrak{p}n)$ bits.*

The ℓ_∞ norm of the velocity vector never grows, as transition matrices only average them out and the noise factors are bounded by 1: since $\mathfrak{p} \geq n^3$, it follows that, for any $t \geq 1$,

$$\|v(t)\|_2 = 2^{O(\mathfrak{p})}. \quad (3)$$

Ergodicity. Ignoring noise, the fundamental motion equation (1) gives the position of the birds at time $t > 1$ as $x(t) = x(0) + (P^*(t-1) \otimes I_d)v(1)$, where

$$P^*(t) = P(1) + P(2)P(1) + P(3)P(2)P(1) + \cdots + P(t) \cdots P(2)P(1).$$

Products of the form $P(t) \cdots P(1)$ appear in many applications [22], including the use of *colored random walks* in space-bounded interactive proof systems [5,6]. One important difference is that random walks correspond to products that grow by multiplication from the right while the dynamics of bird flocking is associated with backward products: the transition matrices evolve by multiplication from the left. This changes the nature of ergodicity. Intuitively, one would expect (if all goes well) that these products should look increasingly like rank-1 matrices. But can the rows continue to vary widely forever though all in lockstep (weak ergodicity), or do they converge to a fixed vector (strong ergodicity)? The two notions are equivalent for backward products but not for the forward kind [22]. Here is an intuitive explanation. Backward products keep averaging the rows, so their entries themselves tend to converge: geometrically, the convex hull of the points formed by the row keeps shrinking. Forward products lack this notion of averaging. For a simple illustration of the difference, consider the three stochastic matrices:

$$A = \frac{1}{2} \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} \quad B = \frac{1}{2} \begin{pmatrix} 2 & 0 \\ 1 & 1 \end{pmatrix} \quad C = \frac{1}{4} \begin{pmatrix} 3 & 1 \\ 3 & 1 \end{pmatrix}.$$

Backward products are given by the simple formula,

$$\underbrace{\cdots ABABABAB}_{n} = C,$$

for all $n > 1$. On the other hand, the forward product tends to a rank-one matrix but never converges:

$$\underbrace{ABABABAB}_{n} \cdots = \begin{cases} C & \text{even } n > 1; \\ A & \text{odd } n > 0, \end{cases}$$

Figure 5: Premultiplying a matrix, whose rows are shown as points, by a stochastic matrix $P(t)$ shrinks its convex hull.

As we just mentioned, the key to ergodicity for backward products resides in the convex hull of the rows. We introduce a family of metrics to measure its

“shrinkage.” For any $p > 1$, let $\tau_p(A)$, the *ergodicity coefficient* of A , denote the ℓ_p -diameter of the convex hull formed by the rows of a matrix A , ie,

$$\tau_p(A) = \max_{i,j} \|A_{i*} - A_{j*}\|_p,$$

where A_{i*} denotes the i -th row of A . From the fact that ℓ_p is a metric space for $p > 1$, it follows by convexity that the diameter is always achieved at vertices of the convex hull. We extend the definition to $p = 1$ but, for reasons soon to be apparent, it is important to keep the coefficients between 0 and 1, so we divide the diameter by two, ie,

$$\tau_1(A) = \frac{1}{2} \max_{i,j} \sum_k |a_{ik} - a_{jk}|.$$

To understand why $\tau_p(A)$ relates to ergodicity, assume that A is row-stochastic. We observe then that

$$0 \leq \tau_1(A) = 1 - \min_{i,j} \sum_k \min\{a_{ik}, a_{jk}\} \leq 1.$$

This follows from the fact that the distance $|a - b|$ between two numbers a, b is twice the difference between their average and the smaller one. There are many fascinating relations between these diameters [22]. For our purposes, the following submultiplicativity result will suffice [14].⁵

LEMMA 3.3. *Given two row-stochastic matrices A, B that can be multiplied,*

$$\tau_2(AB) \leq \tau_1(A)\tau_2(B).$$

Proof. Fix the two rows i, j that define $\tau_2(AB)$, and let $\alpha = 1 - \sum_k \min\{a_{ik}, a_{jk}\}$. Note that $0 \leq \alpha \leq \tau_1(A)$. If $\alpha = 0$, then $A_{i*} = A_{j*}$ and $\tau_2(AB) = 0$, so the lemma holds trivially. Assuming, therefore, that $\alpha > 0$, we derive

$$\begin{aligned} \tau_2(AB) &= \left\| \sum_k a_{ik} B_{k*} - \sum_k a_{jk} B_{k*} \right\|_2 \\ &= \left\| \sum_k (a_{ik} - \min\{a_{ik}, a_{jk}\}) B_{k*} - \sum_k (a_{jk} - \min\{a_{ik}, a_{jk}\}) B_{k*} \right\|_2 \\ &\leq \tau_1(A) \left\| \frac{1}{\alpha} \sum_k (a_{ik} - \min\{a_{ik}, a_{jk}\}) B_{k*} - \frac{1}{\alpha} \sum_k (a_{jk} - \min\{a_{ik}, a_{jk}\}) B_{k*} \right\|_2. \end{aligned}$$

Observe now that the coefficients $\alpha^{-1}(a_{ik} - \min\{a_{ik}, a_{jk}\})$ are nonnegative and sum up to 1, so the corresponding sum is a convex combination of the rows of B . The same is true of the other sum; so, by convexity, the distance between any two of them cannot exceed $\tau_2(B)$. \square

⁵ Submultiplicativity is not true for τ_2 in general. First, to make the notion meaningful, we would need to normalize it and use $\hat{\tau}_2 = \tau_2/\sqrt{2}$ instead, to ensure that $\hat{\tau}_2(A) \leq 1$ for any stochastic A . Unfortunately, $\hat{\tau}_2$ is not submultiplicative, as we easily check by considering a regular random walk A on $K_{2,2}$ and checking that $\hat{\tau}_2(A^2) > \hat{\tau}_2(A)^2$.

Figure 6: $\tau_p(A)$ is the ℓ_p -diameter of the convex hull of the rows of A .

Displacement. For future use, we mention an elementary relation between bird distance and velocity. The *relative displacement* between two birds \mathcal{B}_i and \mathcal{B}_j is defined as $\Delta_{ij}(t) = |\text{DIST}_t(\mathcal{B}_i, \mathcal{B}_j) - \text{DIST}_{t-1}(\mathcal{B}_i, \mathcal{B}_j)|$, where the distance between two birds is denoted by $\text{DIST}_t(\mathcal{B}_i, \mathcal{B}_j) = \|x_i(t) - x_j(t)\|_2$.

LEMMA 3.4. For $t \geq 1$, $\Delta_{ij}(t) \leq \|v_i(t) - v_j(t)\|_2$.

Proof. By the triangle inequality,

$$\|x_i(t) - x_j(t)\|_2 \leq \|x_i(t-1) - x_j(t-1)\|_2 + \|x_i(t) - x_i(t-1) - (x_j(t) - x_j(t-1))\|_2.$$

Reversing the roles of t and $t-1$ gives us a similar inequality, from which we find that

$$|\text{DIST}_t(\mathcal{B}_i, \mathcal{B}_j) - \text{DIST}_{t-1}(\mathcal{B}_i, \mathcal{B}_j)| \leq \|x_i(t) - x_i(t-1) - (x_j(t) - x_j(t-1))\|_2.$$

□

3.2 The Algebra and Geometry of Flocking

To separate the investigation of network switches from the time analysis is one of the key ideas of our method. Our first task, therefore, is to bound the number of times the flocking network can change, while ignoring how long it takes. Next, we investigate the special case of time-invariant networks. In the worst case, the pre-convergence flying time vastly exceeds the number of network switches, so it is quite intuitive that a time-invariant analysis should be critical. Our next task is then to prove the rationality of the limit configuration. We also show why the hysteresis rule is sound. We follow this with an in-depth study of the convex geometry of flocking. We define the *flight net*, and with it derive what

is arguably our most versatile analytical tool: a mathematical statement that captures the intuition that flocks that hope to meet in the future must match their velocities more and more closely over time. To do this we introduce the key concept of a *virtual bird*, which is a bird that can switch identities with its neighbors nondeterministically.

Counting Network Switches. Let $N(n)$ be the maximum number of switches in the flocking network, ie, the number of times t such that $P(t) \neq P(t+1)$. Obviously, $N(1) = 0$; note that, by our requirement that C_t may vary only when G_t does, we could use footprints equivalently in the definition. For the sake of our inductive argument, we need a uniform bound on $N(n)$ over all initial conditions. Specifically, we define $N(n)$ as the largest number of switches of an n -bird flocking network, given arbitrary initial conditions: for the purpose of bounding $N(n)$, $x(0)$ and $v(1)$ are *any real* vectors, with $\|v(1)\|_2 = 2^{O(p)}$. This involves building a quantitative framework around the existential analyses of [8, 13–15]. We now prove the network switching bound claimed in the “Results” section of §1.

LEMMA 3.5. *The maximum number $N(n)$ of switches in the flocking network is bounded by $n^{O(n^3)}(\mathfrak{p} + \log \frac{1}{\varepsilon_h})^{n-1}$.*

COROLLARY 3.6. *Under the default settings (2), $N(n) = n^{O(n^3)}$.*

Proof of Lemma 3.5. We begin with the noise-free model. Fix $s > 0$ once and for all. For $t > s$, let $N(t, s)$ be the number of network changes between times s and t , ie, the number of integers u ($s < u \leq t$) such that $\underline{P}(u) \neq \underline{P}(u-1)$. Since the diagonal of each $P(t)$ is positive, $\underline{P}(t, s)$ can never lose a 1 as t grows, so there exists a smallest T_1 such that $\underline{P}(t, s) = \underline{P}(T_1, s)$ for all $t > T_1$. Consider the first column and let $n_0 < \dots < n_{l_1} \leq n$ be its successive Hamming weights (ie, number of ones); because $p_{11}(s) \neq 0$, $n_0 \geq 1$. We define t_k as the smallest $t \geq s$ such that the first column of $P(t, s)$ acquires weight n_k . Note that $t_0 = s$ and $t_{l_1} \leq T_1$. How large can $N(t_{k+1}, t_k)$ be, for $0 \leq k < l_1$? Let F denote the subgraph of $G_{t_{k+1}}$ consisting of the connected components (ie, flocks) that include the n_k birds indexed by the first column of $\underline{P}(t_k, s)$. Intuitively, at time $t_k + 1$, bird \mathcal{B}_1 can claim it has had influence over the n_k birds since time t_0 . At time $t_k + 2$, this influence will spread further to the neighbors of these n_k birds in F . Note that having been influenced by \mathcal{B}_1 in the past does not imply connectivity among the n_k birds.

- If F contains more than n_k birds then, at time $t_k + 1$, at least one of these extra birds, \mathcal{B}_i , is adjacent in $G_{t_{k+1}}$ to one of the n_k birds, say, \mathcal{B}_j . Then, $p_{ij}(t_k + 1) > 0$ and $p_{j1}(t_k, s) > 0$; hence $p_{i1}(t_k + 1, s) \geq p_{ij}(t_k + 1)p_{j1}(t_k, s) > 0$. Since \mathcal{B}_i is not one of the n_k birds, $p_{i1}(t_k, s) = 0$ and the first column of $\underline{P}(t, s)$ acquires a new 1 between t_k and $t_k + 1$. This implies that $t_{k+1} = t_k + 1$ and $N(t_{k+1}, t_k) \leq 1$.

- Assume now that F has exactly n_k vertices. The flocking network G_{t_k+1} consists of a set of flocks totalling n_k birds and a separate set of flocks including the $n - n_k$ others. The next $N(n_k) + N(n - n_k) + 1$ network switches must include one between the two sets, since by then we must run out of allowable “intra-switches.” It follows by monotonicity of $N(n)$ that

$$N(t_{k+1}, t_k) \leq 1 + N(n_k) + N(n - n_k) \leq 2N(n - 1) + 1.$$

Figure 7: The white birds have all been influenced by \mathcal{B}_1 : on the left, they propagate that influence at the next step; on the right, they have to wait for flocks to join together before the influence of \mathcal{B}_1 can expand further.

In both cases, $N(t_{k+1}, t_k) \leq 2N(n - 1) + 1$, so summing over all $0 \leq k < l_1$,

$$N(t_{l_1}, s) = \sum_{k=0}^{l_1-1} N(t_{k+1}, t_k) \leq 2nN(n - 1) + n.$$

Of course, there is nothing special about bird \mathcal{B}_1 . We can apply the same argument for each column and conclude that the time T_1 when the matrix $\underline{P}(t, s)$ has finally stabilized satisfies

$$N(T_1, s) \leq 2nN(n - 1) + n. \quad (4)$$

The index set V_1 corresponding to the ones in the first column of $\underline{P}(T_1, s)$ is called the first *stabilizer*. For $t > T_1$, no edge of G_t can join V_1 to its complement, since this would immediately add more ones to the first column of $\underline{P}(t, s)$. This means that \mathcal{B}_1 can no longer hope to influence any bird outside of V_1 past time T_1 .

Relabel the rows and columns so that all the ones in $\underline{P}(T_1, s)$'s first column appear on top. Then, for any $t > T_1$, $P(t)$ is a 2-block diagonal matrix with the top left block, indexed by $V_1 \times V_1$, providing the transitions among the vertices

of V_1 at time t . This is a restatement of our observation regarding G_t and V_1 . Here is why. Since the footprint of $P(t)$ is symmetric, it suffices to consider the consequence of a nonzero, nondiagonal entry in $P(t)$, ie, $p_{ij}(t) > 0$, with $i \notin V_1$ and $j \in V_1$. This would imply that

$$p_{i1}(t, s) \geq p_{ij}(t)p_{j1}(t-1, s) > 0,$$

and hence that $i \in V_1$, a contradiction. Being 2-block diagonal is invariant under composition, so $P(t, T_1 + 1)$ is also a matrix of that type. Let $A_{|V \times W}$ denote the submatrix of A with rows indexed by V and columns by W . Writing $V_0 = \{1, \dots, n\}$, for $t > T_1$,

$$P_{|V_1 \times V_0}(t, s) = P_{|V_1 \times V_1}(t, T_1 + 1)P_{|V_1 \times V_0}(T_1, s).$$

By setting s to $T_1 + 1$ we can repeat the same argument, the only difference being that the transition matrices are now $|V_1|$ -by- $|V_1|$. This leads to the second stabilizer $V_2 \subseteq V_1$, which, by relabeling, can be assumed to index the top of the subsequent matrices. We define T_2 as the smallest integer such that $\underline{P}_{|V_1 \times V_1}(t, T_1 + 1) = \underline{P}_{|V_1 \times V_1}(T_2, T_1 + 1)$ for all $t > T_2$. The set V_2 indexes the ones in the first column of $\underline{P}_{|V_1 \times V_1}(T_2, T_1 + 1)$. Iterating in this fashion leads to an infinite sequence of times $T_1 < T_2 < \dots$ and stabilizers $V_1 \supseteq V_2 \supseteq \dots$ such that, for any $t > T_k$,

$$P_{|V_k \times V_0}(t, s) = P_{|V_k \times V_k}(t, T_k + 1)P_{|V_k \times V_{k-1}}(T_k, T_{k-1} + 1) \cdots P_{|V_2 \times V_1}(T_2, T_1 + 1)P_{|V_1 \times V_0}(T_1, T_0 + 1),$$

where $P_{|V_i \times V_{i-1}}(T_i, T_{i-1} + 1)$ is a $|V_i|$ -by- $|V_{i-1}|$ matrix and $T_0 = s - 1$. The stabilizers are the sets under refreshed influence from \mathcal{B}_1 . We illustrate this decomposition below:

$$A = \frac{1}{2} \begin{pmatrix} 2 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 1 & 1 \end{pmatrix} \quad B = \frac{1}{2} \begin{pmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 2 \end{pmatrix} \quad C = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

Consider the word $M = CB^3CABABA$. The matrix $M_{|V_6 \times V_0}$ is factored as

$$C_{|V_6 \times V_5} B_{|V_5 \times V_4} B_{|V_4 \times V_3} (BC)_{|V_3 \times V_2} (AB)_{|V_2 \times V_1} (ABA)_{|V_1 \times V_0},$$

where $V_0 = V_1 = V_2 = \{1, 2, 3\}$, $V_3 = V_4 = V_5 = \{1, 2\}$ and $V_6 = \{1\}$. The factorization looks like this:

$$M_{|V_6 \times V_0} = (1 \ 0) \cdot \frac{1}{2} \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} \cdot \frac{1}{2} \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} \cdot \frac{1}{2} \begin{pmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \end{pmatrix} \cdot \frac{1}{4} \begin{pmatrix} 2 & 2 & 0 \\ 1 & 1 & 2 \\ 1 & 1 & 2 \end{pmatrix} \cdot \frac{1}{8} \begin{pmatrix} 4 & 2 & 2 \\ 2 & 3 & 3 \\ 2 & 3 & 3 \end{pmatrix},$$

with the infinite nested sequence

$$V_1 = \{1, 2, 3\} \supseteq \{1, 2, 3\} \supseteq \{1, 2\} \supseteq \{1, 2\} \supseteq \{1, 2\} \supseteq \{1, 2\} \supseteq \{1\} \supseteq \{1\} \supseteq \{1\} \cdots$$

What is the benefit of rewriting the top rows of $P(t, s)$ in such a complicated manner? The first column of each $P_{|V_i \times V_{i-1}|}(T_i, T_{i-1} + 1)$ consists entirely of positive entries, so the submultiplicativity of the ergodicity coefficients implies rapid convergence of the products toward a rank-one matrix. This has bearing on the relative displacement of birds and groupings into flocks. By Lemma 3.1, each entry in the first column of each $P_{|V_i \times V_{i-1}|}(T_i, T_{i-1} + 1)$ is at least $n^{-O(n^2)}$, so half the ℓ_1 -distance between any two rows is at most $1 - n^{-O(n^2)} \leq e^{-n^{-O(n^2)}}$; therefore

$$\tau_1(P_{|V_i \times V_{i-1}|}(T_i, T_{i-1} + 1)) \leq e^{-n^{-O(n^2)}}.$$

Lemma 3.3 implies that $\tau_2(A) \leq \tau_1(A)\tau_2(I) \leq \sqrt{2}\tau_1(A)$, and

$$\begin{aligned} \tau_2(P_{|V_k \times V_0|}(t, s)) &\leq \sqrt{2}\tau_1(P_{|V_k \times V_k|}(t, T_k + 1)) \prod_{i=1}^k \tau_1(P_{|V_i \times V_{i-1}|}(T_i, T_{i-1} + 1)) \\ &\leq \sqrt{2}e^{-kn^{-O(n^2)}}. \end{aligned} \quad (5)$$

Let $\chi(i, j)$ denote the n -dimensional vector with all coordinates equal to 0, except for $\chi(i, j)_i = 1$ and $\chi(i, j)_j = -1$. Note that

$$v_i(t) - v_j(t) = ((\chi(i, j)P(t-1, 1)) \otimes I_d)v(1);$$

therefore, by Cauchy-Schwarz and (3),

$$\|v_i(t) - v_j(t)\|_2 \leq \sqrt{d}\tau_2(P(t-1, 1))\|v(1)\|_2 \leq \tau_2(P(t-1, 1))2^{O(\mathfrak{p})}. \quad (6)$$

If we restrict i, j to V_k , we can replace $P(t-1, 1)$ by $P_{|V_k \times V_0|}(t-1, 1)$ and write

$$\|v_i(t) - v_j(t)\|_2 \leq \tau_2(P_{|V_k \times V_0|}(t-1, 1))2^{O(\mathfrak{p})}.$$

Setting $k = n^{b_0 n^2} \lceil \mathfrak{p} + \log \frac{1}{\varepsilon_h} \rceil$ for a large enough integer constant $b_0 > 0$, we derive from (5) that, for any $t > T_k + 1$,

$$\max_{i, j \in V_k} \|v_i(t) - v_j(t)\|_2 \leq e^{-kn^{-O(n^2)} + O(\mathfrak{p})} < \varepsilon_h. \quad (7)$$

By Lemma 3.4, it then follows that $\Delta_{ij}(t) < \varepsilon_h$. By the hysteresis rule, this means that if birds \mathcal{B}_i and \mathcal{B}_j are joined after time $T_k + 1$, they will always remain so. This leaves at most $\binom{|V_k|}{2}$ extra network changes (final pairings), so the total number is conservatively bounded by

$$N(T_k, T_{k-1}) + \cdots + N(T_1, 1) + \binom{|V_k|}{2}.$$

But (4) holds for any pair $(T_i, T_{i-1} + 1)$, so

$$N(n) < k(2nN(n-1) + n) + n^2.$$

Since $N(1) = 0$, for all $n > 1$,

$$N(n) = n^{O(n^3)} \left(\mathfrak{p} + \log \frac{1}{\varepsilon_n} \right)^{n-1}.$$

There is a technical subtlety we need to address. In the inductive step defining $N(n-1)$, and more generally $N(n')$ for $n' < n$, the initial conditions and element sizes of the transition matrices should be treated as global parameters: they depend on n , not n' . In fact, it is safe to treat n as a fixed parameter everywhere, except in the recurrence (4). The key observation is that, as n' decreases, the bounds provided by (5) and in the setting of $k = n^{b_0 n^2} \left(\mathfrak{p} + \log \frac{1}{\varepsilon_n} \right)$ still provide valid—in fact, increasingly conservative—estimates as n' decreases. The noise is handled by reapplying the bound after each of the $e^{O(n^3)}$ perturbations. \square

Figure 8: The arborescence of birds separating into groups.

Remark 2.1. The rationality of positions and velocities was never used in the proof. The only requirement is that the initial velocities of the birds should have Euclidean norm in $2^{O(\mathfrak{p})}$.

Remark 2.2. The nested sequence $V_1 \supseteq V_2 \supseteq \dots$ is infinite but the number of different subsets obviously is not. The smallest stabilizer V_i , denoted V_{k_1} to indicate its relation to \mathcal{B}_1 , cannot be empty since a bird influences itself for ever; hence $\{1\} \in V_{k_1}$. If $|V_{k_1}| > 1$, then \mathcal{B}_1 influences all the birds in V_{k_1} recurrently, ie, infinitely often. In fact, this is true not just of \mathcal{B}_1 but of all V_{k_1} , all of whose birds influence all others in that set recurrently. The sets V_{k_1}, \dots, V_{k_n} are therefore

pairwise disjoint or equal. This implies a partition of the bird set into recurrently self-influencing classes. One can model the process leading to it as an arborescence whose root corresponds to the first time the set of n birds is split into two subsets that will no longer influence each other. Iterating in this fashion produces a tree whose leaves are associated with the disjoint V_{k_j} 's. Note that the stabilizers V_1, V_2 , etc, are specific to \mathcal{B}_1 and their counterparts for \mathcal{B}_2 might partly overlap with them (except for the last one); therefore, the path in the tree toward the leaf labeled V_{k_1} cannot be inferred directly from the stabilizers.

Time-Invariant Flocking. Birds are expected to spend most of their time flying in fixed flocks. We investigate this case separately. The benefit is to derive a convergence time that is exponentially faster than in the general case. In this section, $G_t = G$ is time-invariant; for notational convenience, we assume there is a single flock, ie, G_t is connected. The flocking is noise-free. We can express the stochastic matrix P as $I_n - CL$. The corresponding Markov chain is reversible and, because of connectivity, irreducible. The diagonal being nonzero, it is aperiodic, hence ergodic. The transition matrix P has the simple dominant eigenvalue 1 with right and left eigenvectors $\mathbf{1}$ and

$$\pi = \frac{1}{\text{tr } C^{-1}} C^{-1} \mathbf{1},$$

respectively. Lack of symmetry does not keep P from being diagonalizable, though it denies us eigenvector orthogonality. Define

$$M = C^{-1/2} P C^{1/2} = C^{-1/2} (I_n - CL) C^{1/2} = I_n - C^{1/2} L C^{1/2}. \quad (8)$$

Being symmetric, M can be diagonalized as $\sum_{k=1}^n \lambda_k u_k u_k^T$, where the u_k 's are orthonormal eigenvectors and the eigenvalues are real. It follows that P can be diagonalized as well, with the same eigenvalues. By Perron-Frobenius and standard properties of ergodic walks [4, 22], $1 = \lambda_1 > \lambda_2 \geq \dots \geq \lambda_n > -1$ and $u_1 = (\sqrt{\pi_1}, \dots, \sqrt{\pi_n})^T$. Since $\sum_k u_k u_k^T = I_n$, the following identity holds for all nonnegative s , including $s = 0$ (for which we must assume that $0^0 = 1$):

$$P^s = C^{1/2} M^s C^{-1/2} = \mathbf{1} \pi^T + \sum_{k=2}^n \lambda_k^s C^{1/2} u_k u_k^T C^{-1/2}. \quad (9)$$

The left and right eigenvectors of P for λ_k are given (in column form) by $C^{-1/2} u_k$ and $C^{1/2} u_k$ and, together, form inverse matrices; in general, neither group forms an orthogonal basis. We can bound the second largest eigenvalue by using standard algebraic graph theory. We include a proof for completeness.

LEMMA 3.7. *If $\mu \stackrel{\text{def}}{=} \max_{k>1} |\lambda_k|$, then $\mu \leq 1 - n^{-O(1)}$.*

Proof. By the $O(\log n)$ -bit encoding of C , each diagonal of P is at least n^{-b} , for some constant.⁶ The matrix $(1 - \frac{1}{2}n^{-b})^{-1}(P - \frac{1}{2}n^{-b}I_n)$ is stochastic and all of its eigenvalues all lie in $[-1, 1]$. It follows that $\lambda_{n-1} \geq n^{-O(1)} - 1$, for any $k > 1$. Observe now that $1 - \lambda_2$ is the smallest positive eigenvalue of the normalized Laplacian $C^{1/2}LC^{1/2}$. The simplicity of the eigenvalue 0 (by connectivity) implies that any eigenvector of the normalized Laplacian corresponding to a nonzero eigenvalue is normal to $C^{-1/2}\mathbf{1}$; therefore, by Courant-Fischer,

$$1 - \lambda_2 = \min \left\{ x^T C^{1/2} L C^{1/2} x : \mathbf{1}^T C^{-1/2} x = 0 \text{ and } \|x\|_2 = 1 \right\}.$$

Write $y = C^{1/2}x$ and express the system in the equivalent form: $1 - \lambda_2 = \min y^T L y$, subject to (i) $\mathbf{1}^T C^{-1}y = 0$ and (ii) $\|C^{-1/2}y\|_2 = 1$. By using ideas from [4, 12], we argue that, for some m and M , by (i), $y_m \leq 0$, for some m , and from (ii) $y_M \geq (\text{tr } C^{-1})^{-1/2}$. Since G is connected, there exists a path \mathcal{M} of length at most n joining nodes m and M . Thus, by Cauchy-Schwarz, the solution y of the system satisfies:

$$\begin{aligned} 1 - \lambda_2 = y^T L y &= \sum_{(i,j) \in G} (y_i - y_j)^2 \geq \sum_{(i,j) \in \mathcal{M}} (y_i - y_j)^2 \geq \frac{1}{n} \left(\sum_{(i,j) \in \mathcal{M}} |y_i - y_j| \right)^2 \\ &\geq \frac{1}{n} |y_M - y_m|^2 \geq \frac{1}{n(\text{tr } C^{-1})} = n^{-O(1)}. \end{aligned}$$

□

By (9), for all $i, j, s > 0$, $(P^s)_{ij} \geq \pi_j - \sum_{k>1} |\lambda_k|^s \sqrt{c_i/c_j} |(u_k)_i (u_k)_j| \geq \pi_j - n^{O(1)} \mu^s$. A similar derivation gives us the corresponding upper bound; so,⁷ by Lemma 3.7,

$$\|P^s - \mathbf{1}\pi^T\|_F \leq e^{-sn^{-O(1)} + O(\log n)}. \quad (10)$$

Similarly, for $s > n^{c_0}$, for a constant c_0 large enough,

$$\begin{aligned} \tau_1(P^s) &= 1 - \min_{i,j} \sum_{k=1}^n \min \{ (P^s)_{ik}, (P^s)_{jk} \} \\ &\leq 1 - \sum_{k=1}^n (\pi_k - n^{O(1)} e^{-sn^{-O(1)}}) = n^{O(1)} e^{-sn^{-O(1)}} < \frac{1}{2}. \end{aligned} \quad (11)$$

Given a vector ξ in \mathbb{R}^n , consider the random variable X formed by picking the i -coordinate of x with probability π_i . As claimed in the introduction, the variance of X is a quadratic Lyapunov function. This is both well known and intuitively obvious since we are sampling from the stationary distribution of an

⁶ To simplify the notation, constants such as b and c are reused frequently in the text, with their values depending on the context.

⁷ The Frobenius norm $\|M\|_F$ of a matrix is the Euclidean norm of the vector formed by its elements. The property we will use most often is a direct consequence of Cauchy-Schwarz, $\|Mu\|_2 \leq \|M\|_F \|u\|_2$, and more generally the submultiplicativity of the norm.

ergodic Markov chain and then taking one “mixing” step: the standard deviation decreases at a rate given by the Fiedler value. As was observed in [19], because the random variable involves only π and not P , any flock switching that keeps the graph connected with the same stationary distribution admits a common quadratic Lyapunov function. If $\xi = \mathbf{1}$, then obviously, $\mathbf{var}X = 0$. We now show that the variance decays exponentially fast.

LEMMA 3.8. $\mathbf{var}(PX) \leq \mu^2(\mathbf{var}X)$.

Proof. For any ξ , the vector $y = (I_n - \mathbf{1}\pi^T)\xi$ is such that $C^{-1/2}y$ is orthogonal to $u_1 = (\sqrt{\pi_1}, \dots, \sqrt{\pi_n})^T$. Therefore the latter lies in the contractive eigenspace of M and

$$\|M(C^{-1/2}y)\|_2 \leq \mu\|C^{-1/2}y\|_2;$$

hence, by (8),

$$\begin{aligned} (Py)^T C^{-1}(Py) &= (y^T C^{-1/2})(C^{1/2}P^T C^{-1/2})(C^{-1/2}PC^{1/2})(C^{-1/2}y) \\ &= \|MC^{-1/2}y\|_2^2 \leq \mu^2\|C^{-1/2}y\|_2^2. \end{aligned}$$

As a result,

$$(Py)^T C^{-1}(Py) \leq \mu^2 y^T C^{-1}y.$$

Since $\pi = (\text{tr } C^{-1})^{-1}C^{-1}\mathbf{1}$,

$$\mathbf{var}X = \sum_{i=1}^n \pi_i \left(\xi_i - \sum_i \pi \xi_i \right)^2 = \xi^T (I_n - \pi \mathbf{1}^T) \frac{C^{-1}}{\text{tr } C^{-1}} (I_n - \mathbf{1}\pi^T) \xi = y^T \frac{C^{-1}}{\text{tr } C^{-1}} y.$$

Because P commutes with $I_n - \mathbf{1}\pi^T$,

$$\mathbf{var}(PX) = (Py)^T \frac{C^{-1}}{\text{tr } C^{-1}} (Py) \leq \mu^2(\mathbf{var}X),$$

and $\mathbf{var}X$ is the desired Lyapunov function. \square

What both (11) and Lemma 3.8 indicate is that convergence for a time-invariant flock evolves as $e^{-tn^{-O(1)}}$, whereas in general the best we can do is invoke (5) and hope for a convergence speed of the form $e^{-tn^{-O(n^2)}}$, which is exponentially slower.

The Rationality of Limit Configurations. The locations of the birds remain rational at all times. Does this mean that in the limit their configurations remain so? We prove that this is, indeed, the case. We do not do this simply out of curiosity. This will be needed for the analysis of convergence. We cover the case of a time-invariant connected network here and postpone the general case for later. For $t > 0$, we define

$$\Gamma_t = -\mathbf{1}\pi^T t + \sum_{s=0}^{t-1} P^s. \quad (12)$$

It is immediate that Γ_t converges to some matrix Γ , as t goes to infinity. Indeed, by (9),

$$\Gamma = \sum_{s \geq 0} (P^s - \mathbf{1}\pi^T) = \sum_{k > 1} \frac{1}{1-\lambda_k} C^{1/2} u_k u_k^T C^{-1/2}.$$

What is perhaps less obvious is why the limit is rational. We begin with a simple characterization of Γ , which we derive by classical arguments about fundamental matrices for Markov chains [11]. We also provide a more ad hoc characterization (Lemma 3.10) that will make later bound estimations somewhat easier.

LEMMA 3.9. *As $t \rightarrow \infty$, Γ_t converges to $\Gamma = -\mathbf{1}\pi^T + (I_n - P + \mathbf{1}\pi^T)^{-1}$.*

Proof. Because $\mathbf{1}$ and π are respectively right and left eigenvectors of P for the eigenvalue 1, for any integer $s > 0$,

$$(P - \mathbf{1}\pi^T)^s = P^s - \mathbf{1}\pi^T. \quad (13)$$

This follows from the identity

$$\begin{aligned} (P - \mathbf{1}\pi^T)^s &= P^s + \sum_{k=0}^{s-1} (-1)^{s-k} \binom{s}{k} P^k (\mathbf{1}\pi^T)^{s-k} \\ &= P^s + (\mathbf{1}\pi^T) \sum_{k=0}^{s-1} (-1)^{s-k} \binom{s}{k} = P^s - \mathbf{1}\pi^T. \end{aligned}$$

And so, for $t > 1$,

$$\Gamma_t + \mathbf{1}\pi^T = I_n + \sum_{s=1}^{t-1} (P^s - \mathbf{1}\pi^T) = \sum_{s=0}^{t-1} (P - \mathbf{1}\pi^T)^s.$$

Pre-multiplying this identity by the “denominator” that we expect from the geometric sum, ie, $I_n - P + \mathbf{1}\pi^T$, we simplify the telescoping sum, using (13) again,

$$\begin{aligned} (I_n - P + \mathbf{1}\pi^T)(\Gamma_t + \mathbf{1}\pi^T) &= (I_n - P + \mathbf{1}\pi^T) \sum_{s=0}^{t-1} (P - \mathbf{1}\pi^T)^s \\ &= I_n - (P - \mathbf{1}\pi^T)^t = I_n - (P^t - \mathbf{1}\pi^T) \end{aligned}$$

By (9), P^t converges to $\mathbf{1}\pi^T$ as t goes to infinity, so $(I_n - P + \mathbf{1}\pi^T)(\Gamma_t + \mathbf{1}\pi^T)$ converges to the identity. This implies that, for t large enough, the matrix cannot be singular and, hence, neither can $I_n - P + \mathbf{1}\pi^T$. This allows us to write:

$$\Gamma + \mathbf{1}\pi^T = (I_n - P + \mathbf{1}\pi^T)^{-1}.$$

□

There is another characterization of Γ without π in the inverse matrix. We use the notation $(Y | y)$ to refer to the n -by- n matrix derived from Y by replacing its last column with the vector y .

LEMMA 3.10. $\Gamma = (I_n - \mathbf{1}\pi^T | \mathbf{0})(I_n - P | \mathbf{1})^{-1}$.

Proof. Since π is a left eigenvector of P for 1, $\mathbf{1}\pi^T(I_n - P) = 0$; hence, for $t > 0$,

$$I_n - P^t = (I_n + P + \dots + P^{t-1})(I_n - P) = (\Gamma_t + \mathbf{1}\pi^T t)(I_n - P) = \Gamma_t(I_n - P).$$

As $t \rightarrow \infty$, $P^t \rightarrow \mathbf{1}\pi^T$; therefore $\Gamma(I_n - P) = I_n - \mathbf{1}\pi^T$. Since $\mathbf{1}$ lies in the kernel of Γ_t , and hence of Γ , the latter matrix satisfies the relation

$$\Gamma(I_n - P | \mathbf{1}) = (I_n - \mathbf{1}\pi^T | \mathbf{0}). \quad (14)$$

The simplicity of P 's dominant eigenvalue 1 implies that $I_n - P$ is of rank $n - 1$. Since $\mathbf{1} \in \ker(I_n - P)$, the last column of $I_n - P$ is the negative sum of the others; so to get the correct rank the first $n - 1$ columns of $I_n - P$ must be independent. Note that the vector $\mathbf{1}$ is not in the space they span: if, indeed, it were, we would have $\mathbf{1} = (I_n - P)y$, for some $y \in \mathbb{R}^n$. Since $\pi^T(I_n - P) = 0$, this would imply that $1 = \pi^T \mathbf{1} = \pi^T(I_n - P)y = 0$, a contradiction. This is evidence that $(I_n - P | \mathbf{1})$ is of full rank, which, by (14), completes the proof. □

The motion equation (1) becomes, for $t \geq 1$,

$$x(t) = x(0) + \left(\sum_{s=0}^{t-1} P^s \otimes I_d \right) v(1) \quad (15)$$

or, equivalently, by (12),

$$x(t) = x(0) + t((\mathbf{1}\pi^T) \otimes I_d)v(1) + (\Gamma_t \otimes I_d)v(1). \quad (16)$$

We call $\mathbf{m}_\pi[x(t)] = (\pi^T \otimes I_d)x(t)$ the *mass center* of the flock and the vector $\mathbf{m}_\pi[v(1)]$ its *stationary velocity*. The latter is the first spectral (vector) coefficient of the velocity. In our lower bound, we will make it the first Fourier coefficient of the dynamical system. The mass center drifts in space at constant speed along a fixed line in d -space: Indeed, $\pi^T \Gamma_t = 0$, so by (16),

$$\mathbf{m}_\pi[x(t)] = \mathbf{m}_\pi[x(0)] + t\mathbf{m}_\pi[v(1)]$$

and

$$x(t) = \underbrace{x(0)}_{\text{start}} + \underbrace{t(\mathbf{1} \otimes I_d)\mathbf{m}_\pi[v(1)]}_{\text{linear drift}} + \underbrace{(\Gamma_t \otimes I_d)v(1)}_{\text{damped oscillator}}. \quad (17)$$

The oscillations are damped at a rate of $e^{-tn^{-O(1)}}$. (We use the term not in the “harmonic” sense but by reference to the negative eigenvalues that might cause

actual oscillations.) Moving the origin to the mass center of the birds, we express $x(t)$, relative to this moving frame, as

$$x^r(t) = x(t) - (\mathbf{1} \otimes I_d) \mathbf{m}_\pi[x(t)];$$

therefore, by simple tensor manipulation,

$$x(t) = x^r(t) + ((\mathbf{1}\pi^T) \otimes I_d)x(0) + t((\mathbf{1}\pi^T) \otimes I_d)v(1); \quad (18)$$

and, by (16),

$$x^r(t) = x(t) - ((\mathbf{1}\pi^T) \otimes I_d)x(t) = ((I_n - \mathbf{1}\pi^T) \otimes I_d)x(0) + (\Gamma_t \otimes I_d)v(1)$$

and, by Lemma 3.9,

LEMMA 3.11. *If G is connected, the relative flocking configuration $x^r(t)$ converges to the limit*

$$x^r = ((I_n - \mathbf{1}\pi^T) \otimes I_d)x(0) + (\Gamma \otimes I_d)v(1).$$

The mass center of the configuration moves in \mathbb{R}^d at constant speed in a fixed direction.

LEMMA 3.12. *The elements of Γ and the coordinates of the limit configuration x^r are CD-rationals over $O(n \log n)$ and $O(n \log n + \mathfrak{p}n)$ bits, respectively.*

Proof. Let C_b denote the $O(n \log n)$ -bit long product of all the denominators in the diagonal matrix C . The determinant of $(CL | \mathbf{1})$ can be expressed as C_b^{-1} times the determinant N of an n -by- n matrix with $O(\log n)$ -bit integer elements. By the Hadamard bound [30], N is an $O(n \log n)$ -bit integer. For the same reason, each element of $\text{adj}(CL | \mathbf{1})$ is also the product of C_b^{-1} with an $O(n \log n)$ -bit integer; therefore,

$$(I_n - P | \mathbf{1})^{-1} = (CL | \mathbf{1})^{-1} = \frac{\text{adj}(CL | \mathbf{1})}{\det(CL | \mathbf{1})}$$

is of the form N^{-1} times an $O(n \log n)$ -bit integer matrix (since the two appearances of C_b^{-1} cancel out). The same is true of $(I_n - \mathbf{1}\pi^T | \mathbf{0})$: this is because, trivially, $\pi^T = (0, \dots, 0, 1)(I_n - P | \mathbf{1})^{-1}$. Therefore, both $(I_n - \mathbf{1}\pi^T | \mathbf{0})$ and $(I_n - P | \mathbf{1})^{-1}$ are matrices with CD-rational coordinates over $O(n \log n)$ bits. Lemma 3.11, with the formulation of Lemma 3.10 for Γ , completes the proof.

□

This implies that $x(t)$ tends toward $a + bt$, where a, b are rational vectors. Since the number of switches and perturbations is finite, this proves the rationality claim made in §1. □

Soundness of the Hysteresis Rule. We begin with a proof that hysteresis is required to ensure convergence. We build a 4-bird flock in one dimension, whose network cannot converge without a hysteresis rule. The construction can be trivially lifted to any dimension. The speed of the birds will decay exponentially. In real life, of course, the birds would stall. But, as we mentioned earlier, we can add a large fixed velocity to all the birds without altering the flocking process. Stalling, therefore, is a nonissue, here and throughout this work. These are the initial conditions:

$$\begin{cases} x(0) = \frac{1}{16}(0, 8, 21, 29); \\ v(1) = \frac{1}{8}(1, -1, 1, -1). \end{cases}$$

The flocking network alternates between a pair of 2-bird edges and a single 4-bird path, whose respective transition matrices are:

$$\frac{1}{3} \begin{pmatrix} 1 & 2 & 0 & 0 \\ 2 & 1 & 0 & 0 \\ 0 & 0 & 1 & 2 \\ 0 & 0 & 2 & 1 \end{pmatrix} \quad \text{and} \quad \frac{1}{3} \begin{pmatrix} 1 & 2 & 0 & 0 \\ 1 & 1 & 1 & 0 \\ 0 & 1 & 1 & 1 \\ 0 & 0 & 2 & 1 \end{pmatrix}.$$

The beauty of the initial velocity $v(1)$ is that it is a right eigenvector for both flocking networks for the same eigenvalue $-\frac{1}{3}$; therefore, for $t > 0$, $v(t) = (-3)^{1-t}v(1)$ and, by (1),

$$x(t) = x(0) + \sum_{s=1}^t v(s) = x(0) + \frac{3}{4} \left(1 - \left(-\frac{1}{3}\right)^t\right) v(1). \quad (19)$$

It follows that

$$x_{i+1}(t) - x_i(t) = \begin{cases} \frac{1}{16}(5 - (-\frac{1}{3})^{t-1}) & \text{if } i = 1, 3; \\ 1 + \frac{1}{16}(-\frac{1}{3})^{t-1} & \text{if } i = 2. \end{cases}$$

The distance between the first and second birds stays comfortably between $\frac{1}{4}$ and $\frac{1}{2}$; same with birds \mathcal{B}_3 and \mathcal{B}_4 . The distance between the middle birds \mathcal{B}_2 and \mathcal{B}_3 oscillates around 1, so the network forever alternates between one and two connected components. The pairs $(\mathcal{B}_1, \mathcal{B}_3)$ and $(\mathcal{B}_2, \mathcal{B}_4)$ form fixed inter-bird distances of $\frac{21}{16}$, so the flocks are always simple paths. This proves the necessity of hysteresis. As we said earlier, virtually any hysteresis rule would work. Ours is chosen out of convenience.

LEMMA 3.13. *The hysteresis rule is sound: (i) any two birds within unit distance of each other at time t share an edge of G_t ; (ii) no two birds at distance greater than $1 + \gamma_{\varepsilon_h}$ are ever adjacent in G_t , where*

$$\gamma = (\mathfrak{p} + \log \frac{1}{\varepsilon_h})^n n^{O(n^3)}.$$

Figure 9: The flocking network alternates between two configurations forever and never converges.

COROLLARY 3.14. *Under the default settings (2), any two birds within unit distance of each other at time t share an edge of G_t ; on the other hand, no two birds at distance greater than $1 + \sqrt{\varepsilon_h}$ are ever adjacent in G_t .*

Proof of Lemma 3.13. Part (i) is true by definition. To prove part (ii), assume by contradiction that, at time t_0 , two birds \mathcal{B}_i and \mathcal{B}_j are within unit distance of each other but further than 1 apart at time $t_0 + 1$. Write

$$\delta = \varepsilon_h \left(\mathfrak{p} + \log \frac{1}{\varepsilon_h} \right)^n n^{b_0 n^3}, \quad (20)$$

for some large enough constant b_0 . Assume also that the distance is greater than $1 + \delta$ at time $t_1 > t_0$ and that, between t_0 and t_1 , the distance always remains in the interval $(1, 1 + \delta]$ and that the two birds are joined in G_t for all $t \in [t_0, t_1]$. Such conditions would violate soundness, so we show they cannot happen. Obviously, they imply that the distance between the two birds never jumps (up or down) by ε_h or more, since otherwise the hysteresis rule would cease to apply and the edge (i, j) would break. This means that $\Delta_{ij}(t) < \varepsilon_h$, for $t_0 < t \leq t_1$.

Consider the $t_1 - t_0$ relative displacements in the time interval $[t_0, t_1]$. Together they create a displacement in excess of δ . Let $\kappa = e^{O(n^3)}$ be the number of steps witnessing noise. Mark the unit-time intervals within $[t_0, t_1]$ that are associated with relative displacements witnessing a perturbation or a network switch: there are at most $N(n) + \kappa$ of those, each one associated with a displacement less than ε_h , so this leaves us with a total displacement greater than $\delta - \varepsilon_h N(n) - \varepsilon_h \kappa$. This is contributed by no more than $N(n) + \kappa + 1$ runs of consecutive unmarked unit-time intervals. By the pigeonhole principle, one of these runs contributes a total

Figure 10: The distance between two adjacent birds cannot exceed 1 by more than δ before the edge breaks.

displacement of at least $(\delta - \varepsilon_h N(n) - \varepsilon_h \kappa) / (N(n) + \kappa + 1)$. If $[s_0, s_1]$ denotes the corresponding time interval ($t_0 \leq s_0 \leq s_1 \leq t_1$), then G_t remains invariant for all $s_0 \leq t \leq s_1$ and, by Lemma 3.5,

$$\sum_{t=s_0+1}^{s_1} \Delta_{ij}(t) \geq \frac{\delta - \varepsilon_h N(n) - \varepsilon_h \kappa}{N(n) + \kappa + 1} \geq \delta n^{-O(n^3)} (\mathfrak{p} + \log \frac{1}{\varepsilon_h})^{1-n}. \quad (21)$$

We now show that this displacement is too large for two birds in the same time-invariant flock for so long. The edge (i, j) is in the network G_t for all $t \in [s_0, s_1]$, so the two birds \mathcal{B}_i and \mathcal{B}_j are in the same flock during that time period. We already observed that $\tau_2(A) \leq \sqrt{2} \tau_1(A)$. By (6, 11) and Lemmas 3.3, 3.4, it follows that, for $s_0 < t \leq s_1$,

$$\begin{aligned} \Delta_{ij}(t) &\leq \|v_i(t) - v_j(t)\|_2 \leq \tau_2(P(t-1, s_0)) 2^{O(\mathfrak{p})} \leq \tau_1(P^{n^{c_0}}(s_0))^{[(t-s_0)n^{-c_0}]} 2^{O(\mathfrak{p})} \\ &\leq 2^{-[(t-s_0)n^{-c_0}] + O(\mathfrak{p})}. \end{aligned} \quad (22)$$

Technically, the way we phrased it, our derivation assumes that the flock that contains the birds \mathcal{B}_i and \mathcal{B}_j at times s_0 through s_1 includes all the birds. This is only done for notational convenience, however, and the case of smaller flocks can be handled in exactly the same way. By (21, 22) and the hysteresis rule,

$$\begin{aligned} \delta n^{-O(n^3)} (\mathfrak{p} + \log \frac{1}{\varepsilon_h})^{1-n} &\leq \sum_{t=s_0+1}^{s_1} \Delta_{ij}(t) \leq \sum_{t=s_0+1}^{s_1} \min \left\{ \varepsilon_h, 2^{-[(t-s_0)n^{-c_0}] + O(\mathfrak{p})} \right\} \\ &\leq \min_{T>0} \left\{ T \varepsilon_h + 2^{-[Tn^{-c_0}] + O(\mathfrak{p})} \right\}. \end{aligned}$$

Setting $T = 2^n \lceil \mathfrak{p} + \log \frac{1}{\varepsilon_h} \rceil$ leads to

$$\delta \leq \varepsilon_h (\mathfrak{p} + \log \frac{1}{\varepsilon_h})^n n^{b_1 n^3},$$

for some positive constant b_1 independent of the constant b_0 used in the definition (20) of δ . Choosing b_0 large enough thus contradicts our choice of δ . The two birds therefore cannot be both joined and apart by more than $1 + \delta$. \square

The Geometry of Flocking: The Virtual Bird. Can birds fly in giant loops and come back to their point of origin? Are there constraints on their trajectories? We show that, after enough time has elapsed, two birds can be newly joined only if they fly almost parallel to each other. We also prove that they cannot stray too far from each other if they want to get together again in the future. We investigate the geometric structure of flocking and, to help us do so, we introduce a useful device, the *flight net*.

Figure 11: The flight net is formed by joining together the convex polytopes associated with birds' new velocities.

It is convenient to lift the birds into \mathbb{R}^{d+1} by adding time as an extra dimension:⁸ $x(t) \mapsto (x_1(t), \dots, x_d(t), t)^T$; $v(t) \mapsto (v_1(t), \dots, v_d(t), 1)^T$. Since $\mathbf{1}$ is a right eigenvector, this lifting still satisfies the equation of motion. The hysteresis rule kicks in at the same time and in the same manner as before; in fact, the lifting has no bearing whatsoever on the behavior of the birds. The *angular offset* $\angle(x_i(t), v_i(t))$, denoted by $\omega_i(t)$, plays an important role in the analysis.⁹ It represents (roughly) how the trajectory of bird \mathcal{B}_i deviates at time t from what it would

⁸This is not a projectivization.

⁹We use $x_i(t)$ as both a point and a vector, trusting the context to make it obvious which is which.

have been had the bird reached its current position by flying along a straight line. We will show that the angular offset decreases roughly as $(\log t)/t$. This fact has many important consequences.

Instead of following a given bird over time and investigating its trajectory locally, we track an imaginary bird that has the ability to switch identities with its neighbors: this *virtual bird* could be \mathcal{B}_i for a while and then decide, at any time, to become any \mathcal{B}_j adjacent to it in the flock. Or, for a rather implausible but helpful image, think of a bird passing the baton to any of its neighbors: whoever holds the baton is the virtual bird. Its trajectory is highly nondeterministic, as it is allowed to follow any path in the flight net. Although in the end we seek answers that relate to physical birds, virtuality will prove to be a very powerful analytical device. It allows us to answer questions such as: Can a virtual bird fly (almost) along a straight line? How far apart can two birds get if they are to meet again later? Another key idea is to trace the flight path of virtual birds backwards in time. This is how we are able to translate stochasticity into convexity and thus bring in the full power of geometry into the picture. The translation emanates from this simple consequence of the velocity equation, $v(t) = (P(t-1) \otimes I_d)v(t-1)$:

$$v_i(t) \in \text{Conv} \{ v_j(t-1) \mid (i, j) \in G_{t-1} \}.$$

By iterating in this fashion, we create the *flight net* $\mathcal{N}_i(t)$ of bird \mathcal{B}_i at time $t > 0$. It is a connected collection of line segments (ie, a 1-skeleton): $\mathcal{N}_i(t) = \mathcal{N}_i(t, K_t)$, where K_t is a large integer parameter. Specifically, we set

$$K_t = \lceil n^{b_0}(\mathbf{p} + \log t) \rceil \tag{23}$$

for a big enough constant b_0 . The power of the flight net comes from its ability to deliver both kinetic and positional information about the “genealogy” of a bird’s current state. Let K be an arbitrary positive integer; we define $\mathcal{N}_i(t, K)$ inductively as follows. The case $t = 1$ is straightforward: $\mathcal{N}_i(t, K)$ consists of the single line segment $x_i(0)x_i(1)$. Suppose that $t > 1$. We say that time s is *critical* if $s \leq K$ or if, during the time interval $[s - K, s]$, there is a perturbation or a network switch, ie, the velocity of at least one flock is multiplied by $I_m \otimes \hat{\alpha}$ or $G_u \neq G_{u+1}$ for some u ($s - K \leq u \leq s$).

- If t is critical, then $\mathcal{N}_i(t, K)$ consists of the segment $x_i(t-1)x_i(t)$, together with the translates $\mathcal{N}_j(t-1, K) + x_i(t-1) - x_j(t-1)$, for all $(i, j) \in G_{t-1}$ and $j = i$.
- If t is noncritical, then $\mathcal{N}_i(t, K)$ consists of the segment $x_i(t-1)x_i(t)$, together with $\mathcal{N}_i(t-1, K)$.

Every flight net has an *antenna* sitting on top, which is a line segment extending from $X_{d+1} = t-1$ to $X_{d+1} = t$ in the case of $\mathcal{N}_i(t, K)$. In the noncritical case, the antenna is connected on top of the previous one, ie, the one for $\mathcal{N}_i(t-1, K)$. Otherwise, we slide the time- $(t-1)$ flight nets of the adjacent birds so that their

Figure 12: In the critical case, the virtual net is translated from bird \mathcal{B}_j to bird \mathcal{B}_i by the baton-passing drift.

antennas join with the bottom vertex of the new antenna: this shift is called the *baton-passing drift*.

Here is the intuition. Flying down the top antenna of the net, the virtual bird hits upon another antenna: either there is only one to choose from, in which case it is almost collinear (because of noncriticality, the corresponding random walk is thoroughly mixed) or else the virtual bird discovers a whole bouquet of antennas and picks one of them. Because the old antenna is a convex combination of the new ones, the virtual bird can continue its backward flight by choosing from a convex cone of directions: this freedom is the true benefit of convexity and, hence, stochasticity. This is when the baton is passed: the virtual bird changes its correspondence with an actual bird as it chooses one of these directions. Because of the translation by $x_i(t-1) - x_j(t-1)$, this change of correspondence is accompanied by a shift of length at most one, what we dub the baton-passing drift.

Viewed from a suitable perspective, the flight net provides a quasi-convex structure from which all sorts of metric information can be inferred. Most important, it yields the crucial *Escape Lemma*, which implies that, as time goes by, it becomes increasingly easy to predict the velocity of a bird from its location, and vice versa. The lemma asserts that the bird flies in a direction that points increasingly away from its original position. We begin with a simple observation. For any time $t > 0$, the $(d + 1)$ -dimensional vector

$$w_i(t) = \frac{1}{t}x_i(t) \tag{24}$$

represents the constant velocity that bird \mathcal{B}_i would need to have if it were to leave the origin at time 0 and be at position $x_i(t)$ at time t while flying in a fixed

direction. Recall that the angular offset $\omega_i(t)$ is $\angle(x_i(t), v_i(t))$; we show that it cannot deviate too much from the *velocity offset* $\|v_i(t) - w_i(t)\|_2$.

Figure 13: Proving that angular and velocity offsets are closely aligned.

LEMMA 3.15. *For any $t > 0$,*

$$2^{-O(\mathfrak{p})} \|v_i(t) - w_i(t)\|_2 \leq \omega_i(t) \leq O(\|v_i(t) - w_i(t)\|_2).$$

Proof. Consider the triangle ABC formed by identifying \overrightarrow{AB} with $v_i(t)$ and \overrightarrow{AC} with $w_i(t)$, and let α, β, γ be the angles opposite BC, CA, AB , respectively. Note that $\alpha = \omega_i(t)$ and $\|v_i(t) - w_i(t)\|_2 = |BC|$. Assume that $\beta \leq \gamma$; we omit the other case, which is virtually identical. By (3), AB and AC have length between 1 and $2^{O(\mathfrak{p})}$; therefore, if $\alpha \neq 0$ then $2^{-O(\mathfrak{p})} \leq \beta < \pi/2$. The proof follows from the law of sines, $|BC|^{-1} \sin \alpha = |AC|^{-1} \sin \beta$. \square

LEMMA 3.16. (**Escape Lemma**) *For any bird \mathcal{B}_i , at any time $t > 0$,*

$$\omega_i(t) \leq \frac{\log t}{t} n^{O(n^3)} (\mathfrak{p} + \log \frac{1}{\varepsilon_n})^{n-1} + \frac{1}{t} \left(2^{O(\mathfrak{p})} + \mathfrak{p} n^{O(n^3)} (\mathfrak{p} + \log \frac{1}{\varepsilon_n})^{n-1} \right).$$

COROLLARY 3.17. *Under the default settings (2), at any time $t > 1$,*

$$\omega_i(t) \leq \frac{\log t}{t} n^{O(n^3)}.$$

Figure 14: Birds fly increasingly in “escape” mode.

Unlike the other factors in the upper bound, the presence of $\log t$ is an artifact of the proof and might not be necessary. Our approach is to exploit the “convexity” of single-bird transitions. One should be careful not to treat flocks as *macro-birds* and expect convexity from stationary velocities. In premixing states, all sorts of “nonconvex” behavior can happen. For example, consider two flocks in dimension 1, both with positive stationary velocities. Say the one on the left has higher speed and catches up with the one on the right to merge into one happy flock. It could be the case that the stationary velocity of the combined flock is negative, ie, the joint flock moves left even though each one of the two flocks was collectively moving right prior to merging. Of course, this a premixing aberration that we would not expect in the long run.

Proof of Lemma 3.16. From the initial conditions, we derive a trivial upper bound of $2^{O(p)}$ for constant t , so we may assume that t is large enough and $\omega_i(t) > 0$. The line passing through $x_i(t)$ in the direction of $v_i(t)$ intersects the hyperplane $X_{d+1} = 0$ in a point p at distance from the origin, $\|p\|_2 = \Omega(t\omega_i(t))$. Recall that the bird \mathcal{B}_i started its journey at distance $2^{O(p)}$ from the origin. If it had flown in a straight line, then we would have $p = x_i(0)$, hence $\omega_i(t) = \frac{1}{t}2^{O(p)}$, and we would be done. Chances are the bird did not fly straight, however. If not, then we exhibit a virtual bird that (almost) does, at least in the sense that it does not get much closer to the origin at time 0 than a straightline flight would. The idea is to use the flight net to follow the trajectory of a virtual bird that closely mimics a straight flight from p to $x_i(t)$.

Some words of intuition. If all times were critical and no perturbation ever took place, then it would be easy to prove by backward induction that, for all $0 \leq s < t$, the segment $px_i(t)$ intersects each hyperplane $X_{d+1} = s$ in a point that lies within the convex hull of $\mathcal{N}_i(t) \cap \{X_{d+1} = s\}$. This would imply that p lies in the convex hull of the birds at time 0, which again would give us the same

lower bound on $\omega_i(t)$ as above (modulo the baton-passing drift). In fact, it would be possible to trace a *shadow path* from $x_i(t)$ down the flight net that leads to a virtual bird at time 0 that is even further away from the origin than p . (We use here a fundamental property of convexity, that no point can be further to a point in a convex polytope than to all of its vertices.) Unfortunately, this convexity argument breaks down because of the net’s jagged paths over noncritical time periods. The jaggedness is so small, however, that it provides us enough “quasi-convexity” to rescue the argument.

Figure 15: The shadow path attempts to follow the segment $px_i(t)$ closely.

First we describe the shadow path; then we show why it works. Instead of handling convexity in \mathbb{R}^{d+1} , we will find it easier to do this in projection. By Lemma 3.15, there exists a coordinate axis, say X_1 , such that

$$0 < \omega_i(t) = O(v_i(t)_1 - w_i(t)_1). \quad (25)$$

Note that we may have to reverse the sign of $v_i(t)_1 - w_i(t)_1$, but this is immaterial. The shadow path $x_i^v(t), x_i^v(t-1), \dots, x_i^v(0)$ describes the flight of the virtual bird \mathcal{B}_i^v backwards in time. The first two vertices are $x_i^v(t) = x_i(t)$ and $x_i^v(t-1) = x_i(t-1)$. This means the virtual bird flies down the topmost edge of $\mathcal{N}_i(t)$, ie, in the negative X_{d+1} direction. Next, the following rule applies for $s = t, t-1, \dots, 2$:

- If s is noncritical, $\mathcal{N}_i(t)$ has a single edge $y_{s-2}y_{s-1}$, with $(y_{s-2})_{d+1} = s-2$. The virtual bird flies down $y_{s-2}y_{s-1}$ and we set $x_i^v(s-2) = y_{s-2}$ accordingly.
- If s is critical, $\mathcal{N}_i(t)$ has one or several edges $y_{s-2}^k y_{s-1}$, with $(y_{s-2}^k)_{d+1} = s-2$. The virtual bird follows the edge with maximum X_1 -extant, ie, the one that

maximizes $(y_{s-1})_1 - (y_{s-2}^k)_1$. (Recall that, although neither y_{s-1} nor y_{s-2}^k might be the position of any actual bird, their difference $y_{s-1} - y_{s-2}^k$ is the velocity vector $v_j(s-1)$ of some \mathcal{B}_j .) We set $x_i^v(s-2) = y_{s-2}^k$.

Figure 16: Following the red shadow path.

The virtual bird thus moves down the flight net back in time until it lands at $X_{d+1} = 0$. The resulting collection of $t+1$ vertices forms the shadow path of the virtual bird \mathcal{B}_i^v at time t . Naturally, we define the velocity of \mathcal{B}_i^v at time $s > 0$ as $v_i^v(s) = x_i^v(s) - x_i^v(s-1)$. Note that $v_i^v(t) = v_i(t)$. To prove that the shadow path does not stray far from the straightline flight from $x_i(t)$ to p , we focus on the difference

$$V_s = v_i^v(s)_1 - w_i(t)_1, \quad (26)$$

for $s \geq 1$. If we could show that V_s is always nonnegative then, measured in projection along the X_1 axis, the virtual bird would fly back in time even further away from the origin that it would if it flew straight from $x_i(t)$ to the hyperplane $X_{d+1} = 0$ in the direction of $-v_i(t)$. Except for the fact that a virtual bird at time 0 may not share the location of any actual bird (an issue we will address later), this would entirely rescue our initial argument. We cannot quite ensure the nonnegativity of V_s , but we come close enough to serve our purposes.

Consider an interval $[r, s]$ consisting entirely of noncritical times (hence $r > K_t$). The flock that contains the virtual bird \mathcal{B}_i^v is invariant between times $r - K_t$ and s and undergoes no perturbation during that period; furthermore, \mathcal{B}_i^v has the same incarnation as some fixed \mathcal{B}_j during the time period $[r-1, s]$. If $\chi(j)$ denotes the n -dimensional vector with all coordinates equal to 0, except for $\chi(j)_j = 1$, then, for $r-1 \leq u \leq s$,

$$v_j(u) = ((\chi(j))^T P^{u-r+K_t}) \otimes I_d v(r - K_t).$$

We abuse notation and restrict P and $v(r - K_t)$ to the flock of \mathcal{B}_j and not to all of $G_{r-K_t} = \dots = G_s$. By (3, 10), we find that

$$\begin{aligned} |v_j(u)_1 - (\mathbf{m}_\pi[v(r - K_t)])_1| &\leq \|((\chi(j)P^{u-r+K_t}) \otimes I_d) - (\pi^T \otimes I_d)v(r - K_t)\|_2 \\ &\leq \sqrt{d} \|P^{u-r+K_t} - \mathbf{1}\pi^T\|_F \|v(r - K_t)\|_2 \\ &\leq e^{-(u-r+K_t)n^{-O(1)}+O(\mathfrak{p}+\log n)}. \end{aligned}$$

We conclude that

$$\begin{aligned} |V_{r-1} - V_s| &= |v_i^v(r-1)_1 - v_i^v(s)_1| = |v_j(r-1)_1 - v_j(s)_1| \\ &\leq |v_j(r-1)_1 - (\mathbf{m}_\pi[v(r - K_t)])_1| + |v_j(s)_1 - (\mathbf{m}_\pi[v(r - K_t)])_1|; \end{aligned}$$

hence, using $\mathfrak{p} \geq n^3$,

$$|V_{r-1} - V_s| \leq e^{-K_t n^{-O(1)}+O(\mathfrak{p})}. \quad (27)$$

As usual, $\kappa = e^{O(n^3)}$ denotes the number of steps witnessing noise. Suppose now that $s > 1$ is critical. If no perturbation occurs at time $s - 1$, then $v_i^v(s)$ is a convex combination of the vectors of the flight net joining $X_{d+1} = s - 2$ to $X_{d+1} = s - 1$. By construction, it follows that

$$v_i^v(s-1)_1 \geq v_i^v(s)_1.$$

If the vector is perturbed by ζ , then

$$v_i^v(s-1)_1 \geq v_i^v(s)_1 - \zeta_1 \geq v_i^v(s)_1 - \delta_{s-1},$$

where $\delta_t = \frac{\log t}{t} e^{O(n^3)}$ (the perturbation bound). In both cases, therefore, $V_{s-1} \geq V_s - \delta_{s-1}$. Let \mathfrak{C} be the number of critical times. By (27), for all $1 \leq s \leq t$,

$$V_s \geq V_t - \mathfrak{C} e^{-K_t n^{-O(1)}+O(\mathfrak{p})} - \sum_{u=s}^{t-1} \delta_u.$$

Summing over all s ,

$$\sum_{s=1}^t V_s \geq tV_t - (t-1)\mathfrak{C} e^{-K_t n^{-O(1)}+O(\mathfrak{p})} - \sum_{s=1}^{t-1} s\delta_s.$$

Since, by assumption, $\delta_s = 0$ at all but κ places,

$$\sum_{s=1}^{t-1} s\delta_s = \kappa e^{O(n^3)} \log t.$$

By (25), $V_t = v_i^v(t)_1 - w_i(t)_1 = \Omega(\omega_i(t))$; therefore,

$$\omega_i(t) = O(V_t) = \frac{O(1)}{t} \left| \sum_{s=1}^t V_s \right| + \mathfrak{C} e^{-K_t n^{-O(1)}+O(\mathfrak{p})} + \frac{\log t}{t} \kappa e^{O(n^3)}. \quad (28)$$

By (24, 26),

$$\begin{aligned} \sum_{s=1}^t V_s &= \sum_{s=1}^t \left\{ x_i^v(s)_1 - x_i^v(s-1)_1 - w_i(t)_1 \right\} = x_i^v(t)_1 - x_i^v(0)_1 - t w_i(t)_1 \\ &= x_i^v(t)_1 - x_i(t)_1 - x_i^v(0)_1 = -x_i^v(0)_1. \end{aligned}$$

Since $x_i^v(0)_1$ is the position of a virtual bird at time 0, it is tempting to infer that it is also the position of some actual bird at that time; hence $|x_i^v(0)_1| = 2^{O(\mathfrak{p})}$. This is not quite true because adding together the velocity vectors ignores the baton-passing drift, ie, the displacements caused by switching birds. At critical times, the virtual bird gets assigned a new physical bird that is adjacent to its currently assigned feathered creature. Recall how the net $\mathcal{N}_j(t-1, K)$ is translated by $x_i(t-1) - x_j(t-1)$. Since $(i, j) \in G_{t-1}$, this causes a displacement of at most 1. Note that unlike the velocity perturbations, whose effects are multiplied by time, the drift is additive. This highlights the role of the flight net as both a kinetic and a positional object. Summing them up, we find that $|x_i^v(0)_1| \leq \mathfrak{C} + 2^{O(\mathfrak{p})}$; hence

$$\left| \sum_{s=1}^t V_s \right| \leq \mathfrak{C} + 2^{O(\mathfrak{p})}. \quad (29)$$

Recall that a time is critical if there exists either a perturbation or a network switch in the past K_t steps. Recall (23) that $K_t = \lceil n^{b_0}(\mathfrak{p} + \log t) \rceil$ for a large enough constant b_0 . By Lemma 3.5, this bounds the number of critical times by

$$\mathfrak{C} \leq K_t(N(n) + \kappa) \leq (\mathfrak{p} + \log t) n^{O(n^3)} (\mathfrak{p} + \log \frac{1}{\varepsilon_h})^{n-1},$$

and the lemma follows from (28, 29). \square

We mention a few other corollaries of Lemma 3.16 that rely on the model's assumptions. Again, recall that the sole purpose of these assumptions is to alleviate the notation and help one's intuition.

COROLLARY 3.18. *Under the default settings (2), at any time $t > 1$, a bird turns by an angle $\angle(v_i(t), v_i(t+1))$ that is at most*

$$\frac{\log t}{t} n^{O(n^3)}.$$

Proof. By (3) and $\delta_t = \frac{\log t}{t} e^{O(n^3)}$, no bird can take a step longer than $2^{O(\mathfrak{p})}$, therefore the angle between the vectors $x_i(t)$ and $x_i(t+1)$ is at most $\frac{1}{t} 2^{O(\mathfrak{p})}$. As a result,

$$\begin{aligned} \angle(v_i(t), v_i(t+1)) &\leq \angle(v_i(t), x_i(t)) + \angle(x_i(t), x_i(t+1)) + \angle(x_i(t+1), v_i(t+1)) \\ &= \omega_i(t) + \angle(x_i(t), x_i(t+1)) + \omega_i(t+1), \end{aligned}$$

and the proof follows from Corollary 3.17. The property we are using here is the triangle inequality for angles: equivalently, the fact that, among the 3 angles around a vertex of a tetrahedron in \mathbb{R}^3 , none can exceed the sum of the others. Even though the birds live in higher dimension, our implicit argument involves only 3 points at a time and therefore belongs in \mathbb{R}^3 . \square

COROLLARY 3.19. *Under the default settings (2), if two birds are adjacent in the flocking network at time $t > 1$, their distance prior to t always remains within $n^{O(n^3)} \log t$.*

Proof. For reasons discussed above, any two birds are within distance $2^{O(p)}$ after a constant number of steps, so we may assume that t is large enough. Consider the time s that maximizes the distance R_s , for all $s \in [0, t-1]$, between the points $x_i(s)$ and $p = (s/t)x_i(t)$ in the hyperplane $X_{d+1} = s$. For the same reason, we may assume that $s > 1$. By Corollaries 3.17, 3.18,

$$\angle(x_i(s), v_i(s+1)) \leq \omega_i(s) + \angle(v_i(s), v_i(s+1)) \leq \frac{\log s}{s} n^{O(n^3)}. \quad (30)$$

Set up an orthogonal coordinate system in the plane spanned by $O, p, x_i(s)$: O is the origin; the X -axis lies in the hyperplane $X_{d+1} = 0$ and runs in the direction from p to $x_i(s)$; the Y -axis is normal to OX in the $O, p, x_i(s)$ plane. By (3), the Y -coordinate p_Y of p satisfies

$$s \leq p_Y \leq s2^{O(p)}.$$

Let $Y = X \tan \alpha$ and $Y = X \tan \beta$ be the two lines through the origin passing through $x_i(t)$ and $x_i(s)$, respectively. Setting $Y = p_Y$ we find that $p_X = p_Y / \tan \alpha$ and $x_i(s)_X = p_X / \tan \beta$; therefore

$$R_s \leq \left| \frac{1}{\tan \beta} - \frac{1}{\tan \alpha} \right| s2^{O(p)} \leq \frac{\sin(\alpha - \beta)}{(\sin \alpha)(\sin \beta)} s2^{O(p)}.$$

By construction, the velocity $v_i(s+1)$ cannot take the bird \mathcal{B}_i outside the elliptical cylinder that is centered at the line $(O, x_i(t))$ with the point $x_i(s)$ on its boundary and that intersects $X_{d+1} = 0$ in a disk of radius $R_s = |px_i(s)|$. It follows that the normal projection w of $v_i(s+1)$ on the (X, Y) -plane forms an angle γ with $x_i(s)$ at least equal to the angle between the two lines $Y = X \tan \alpha$ and $Y = X \tan \beta$, which is $\alpha - \beta$. By (30), therefore,

$$\alpha - \beta \leq \gamma \leq \angle(x_i(s), v_i(s+1)) \leq \frac{\log s}{s} n^{O(n^3)}.$$

Birds are at most $2^{O(p)}$ away from the origin at time 0 and, by (3), take no step larger than that bound. It follows that both α and β are at least $2^{-O(p)}$, therefore

$$R_s \leq 2^{O(p)} n^{O(n^3)} \log t.$$

If two birds \mathcal{B}_i and \mathcal{B}_j share an edge in a flock at time t , then $\|x_i(t) - x_j(t)\|_2 \leq 1$; so, by the triangle inequality, at any time $1 < s \leq t$,

$$\|x_i(s) - x_j(s)\|_2 \leq 2^{O(p)} n^{O(n^3)} \log t + \frac{s}{t} \|x_i(t) - x_j(t)\|_2,$$

which, by the default settings (2), proves the lemma. \square

Figure 17: Two birds can't stray too far from each other if they're ever to meet again.

Suppose that birds \mathcal{B}_i and \mathcal{B}_j are distance at most D at time $t > 0$. (No assumption is made whether they belong to the same flock or whether (2) holds.) By (24) and Lemmas 3.4, 3.15, 3.16,

$$\begin{aligned} \Delta_{ij}(t) &\leq \|v_i(t) - v_j(t)\|_2 \\ &\leq \|v_i(t) - \frac{1}{t}x_i(t)\|_2 + \|v_j(t) - \frac{1}{t}x_j(t)\|_2 + \frac{1}{t}\|x_i(t) - x_j(t)\|_2 \\ &\leq (\omega_i(t) + \omega_j(t))2^{O(p)} + \frac{D}{t}. \end{aligned} \quad (31)$$

COROLLARY 3.20. *Under the default settings (2), at any time $t > 1$, the difference in stationary velocities between two distinct flocks joining into a common one at time $t + 1$ has Euclidean norm at most $\frac{\log t}{t} n^{O(n^3)}$.*

Proof. The stationary velocity of a flock is a convex combination of its constituents' individual velocities, so the difference in stationary velocities cannot exceed, length-wise, the maximum difference between individual ones. By (3) and the connectivity of flocks, the distance at time t between any two birds in the common flock at time $t + 1$ cannot exceed $D = n + 2^{O(p)}$. The lemma follows from (31) and Corollary 3.17. \square

We define the *fragmentation breakpoint* t_f as

$$t_f = \frac{1}{\varepsilon_h} c_f^{\mathbf{p}} n^{c_f n^3} (\mathbf{p} + \log \frac{1}{\varepsilon_h})^n, \quad (32)$$

where c_f is a large enough constant. Setting $D = 1$ in (31), we find that, by hysteresis and the Escape Lemma, the edges of G_t can break only if $t < t_f$. Past the fragmentation breakpoint, flocks can only merge.

LEMMA 3.21. *At any time $t \geq t_f$, the flocking network G_t may gain new edges but never lose any.*

The Escape Lemma tells us that, after the fragmentation breakpoint, birds fly almost in a straightline and both their positions and velocities can be predicted with low relative error. From a physical standpoint, *they have already converged*. The flocking network may still change, however. It may keep doing so for an unbelievably long time. This is what we show in the next section. Note that, under the default settings of (2), the fragmentation breakpoint t_f is $n^{O(n^3)}$.

3.3 Iterated Exponential Growth

To pinpoint the exact convergence time requires some effort, so it is helpful to break down the task into two parts. We begin with a proof that the flocking network reaches steady state after a number of steps equal to a tower-of-twos of linear height. This allows us to present some of the main ideas and prepare the grounds for the more difficult proof of the logarithmic height in §3.4. The main tools we use in this section are the rationality of limit configurations and root separation bounds from elimination theory. Our investigation focuses on the post-fragmentation phase, ie, $t > t_f$. We do not yet adopt the assumptions of (2); in particular, we use the definition of t_f given in (32).

LEMMA 3.22. *Consider two birds adjacent at time t but not $t - 1$. Assume that the flocks that contain them remain invariant and noise-free during the period $[t_1, t - 1]$, where $t_f < t_1 < t - 1$. If, at time $t - 1$, the birds are in different flocks with distinct stationary velocities, then $t \leq n^{O(t_1^n)}$; otherwise, $t \leq t_1 2^{n^{O(1)}}$.*

Proof. Assume that the flocking network G_t stays invariant during the period $[t_1, t - 1]$. Consider two birds \mathcal{B}_i and \mathcal{B}_j that are adjacent in G_t but not during $[t_1, t - 1]$. The two birds may or may not be in the same flock at time $t - 1$. Let the flock for \mathcal{B}_i (resp. \mathcal{B}_j) consist of m (resp. m') birds: $m = m'$ if the birds are in the same flock, else $m + m' \leq n$. By abuse of notation, we use the terminology of (9), ie, P , π , C , u_k , λ_k , as well as $v(t)$, to refer to the flock of m birds, and we add primes to distinguish it from the flock of \mathcal{B}_j . We wish to place an upper bound on $t - t_1$. Let $\chi(i)$ denote the m -dimensional vector with all coordinates

equal to 0, except for $\chi(i)_i = 1$. By (9, 15), for $t > t_1$,

$$\begin{aligned} x_i(t) &= x_i(t_1) + \left(\sum_{s=0}^{t-t_1-1} (\chi(i)^T P^s) \otimes I_d \right) v(t_1 + 1) \\ &= x_i(t_1) + (t - t_1)y + \sum_{k=2}^m \frac{1 - \lambda_k^{t-t_1}}{1 - \lambda_k} \Phi_k, \end{aligned}$$

where

$$\begin{cases} y = (\pi^T \otimes I_d)v(t_1 + 1) = \mathbf{m}_\pi[v(t_1 + 1)]; \\ \Phi_k = ((\chi(i)^T C^{1/2} u_k u_k^T C^{-1/2}) \otimes I_d)v(t_1 + 1). \end{cases} \quad (33)$$

Note that, by (9, 12),

$$\begin{aligned} \sum_{k=2}^m \frac{1}{1 - \lambda_k} \Phi_k &= \lim_{t \rightarrow \infty} \sum_{s=0}^{t-1} \sum_{k=2}^m \lambda_k^s ((\chi(i)^T C^{1/2} u_k u_k^T C^{-1/2}) \otimes I_d)v(t_1 + 1) \\ &= \lim_{t \rightarrow \infty} \sum_{s=0}^{t-1} ((\chi(i)^T (P^s - \mathbf{1}\pi^T)) \otimes I_d)v(t_1 + 1) \\ &= ((\chi(i)^T \Gamma) \otimes I_d)v(t_1 + 1); \end{aligned}$$

therefore,

$$x_i(t) = x_i(t_1) + ((\chi(i)^T \Gamma) \otimes I_d)v(t_1 + 1) + (t - t_1)y - \sum_{k=2}^m \lambda_k^{t-t_1} \frac{\Phi_k}{1 - \lambda_k}.$$

Adding primes to distinguish between the flocks of \mathcal{B}_i and \mathcal{B}_j (if need be), we find that

$$x_i(t) - x_j(t) = A + B(t - t_1) - \sum_{k=1}^{m_0} \Psi_k \mu_k^{t-t_1}, \quad (34)$$

where

- (i) $A = x_i(t_1) - x_j(t_1) + ((\chi(i)^T \Gamma) \otimes I_d)v(t_1 + 1) - ((\chi'(j)^T \Gamma') \otimes I_d)v'(t_1 + 1)$: By Lemma 3.2, the vectors $v(t_1 + 1)$, $v'(t_1 + 1)$, $x_i(t_1)$, and $x_j(t_1)$ have CD-rational coordinates over $O(t_1 n \log n + \mathfrak{p}n)$ bits, which is also $O(t_1 n \log n)$, since, by (32), $t_1 > t_f > \mathfrak{p}$. In view of Lemma 3.12, this implies that the same is true of the vector A .
- (ii) $B = y - y'$: The stationary distribution $\pi = (\text{tr } C^{-1})^{-1} C^{-1} \mathbf{1}$ is a CD-rational vector over $O(n \log n)$ bits. Together with Lemma 3.2, this implies that B has CD-rational coordinates over $O(t_1 n \log n)$ bits; hence either $B = 0$ or $\|B\|_2 \geq n^{-O(t_1 n)}$.
- (iii) $\mu_1 \geq \dots \geq \mu_{m_0}$: Each μ_k is an eigenvalue λ_l or λ'_l ($l, l' > 1$) and $|\mu_k| < 1$. Their number m_0 is either $m - 1$ (if the two birds \mathcal{B}_i and \mathcal{B}_j belong to the same flock) or $m + m' - 2$, otherwise.

(iv) Each Ψ_k is a d -dimensional vector of the form $\Phi_l/(1 - \lambda_l)$ or $-\Phi'_l/(1 - \lambda'_l)$. Since the eigenvalues are bounded away from 1 by $n^{-O(1)}$ (Lemma 3.7), it follows from (3), the submultiplicativity of the Frobenius norm, and $\mathfrak{p} \geq n^3$ that $\|\Psi_k\|_2 = 2^{O(\mathfrak{p})}$. In the same vein, we note for future reference that

$$\left\| \sum_{k=1}^{m_0} \Psi_k \mu_k^{t-t_1} \right\|_2 \leq e^{-(t-t_1)n^{-O(1)} + O(\mathfrak{p})} = 2^{O(\mathfrak{p})}. \quad (35)$$

We distinguish among three cases:

Case I. $B \neq 0$: The two flocks must be distinct, for having the two birds in the same flock would imply that $\pi = \pi'$ and $v(t_1 + 1) = v'(t_1 + 1)$; hence $y = y'$. By (i, ii), $\|A\|_2 \leq n^{O(t_1n)}$ and $\|B\|_2 \geq n^{-O(t_1n)}$. If the two birds are to be joined in G_t , then $\text{DIST}_t(\mathcal{B}_i, \mathcal{B}_j) = \|x_i(t) - x_j(t)\|_2 \leq 1$. By (32), $t_1 > t_f > \mathfrak{p}$; hence $2^{O(\mathfrak{p})} = n^{O(t_1n)}$. It follows from (33, 35) that $t - t_1 \leq n^{O(t_1n)}$. Note that, for the lower bound of $n^{-O(t_1n)}$ on $\|B\|_2$ to be tight, the flock would have to be able to generate numbers almost as small as Lemma 3.2 allows. For this to happen, energy must shift toward the dominant eigenvalue. This spectral shift occurs only in a specific context, which we examine in detail in the next section.

Case II. $B = 0$ and $\|A\|_2 \neq 1$: By (i), $\|A\|_2$ is bounded away from 1 by $n^{-O(t_1n)}$. It follows from (34, 35) and the triangle inequality that

$$\begin{aligned} \left| \|x_i(t) - x_j(t)\|_2 - 1 \right| &\geq \left| \|A\|_2 - 1 \right| - \left| \|x_i(t) - x_j(t)\|_2 - \|A\|_2 \right| \\ &\geq n^{-O(t_1n)} - \left\| \sum_k \Psi_k \mu_k^{t-t_1} \right\|_2 \\ &\geq n^{-O(t_1n)} - e^{-(t-t_1)n^{-O(1)} + O(\mathfrak{p})}. \end{aligned}$$

Since $t_1 > \mathfrak{p}$, this implies that, for a large enough constant b_0 , the distance between the two birds remains bounded away from 1 by $n^{-O(t_1n)}$ at any time $s \geq t_1 n^{b_0}$. Not only that, but the sign of $\text{DIST}_s(\mathcal{B}_i, \mathcal{B}_j) - 1$ can no longer change after time $t_1 n^{b_0}$. Indeed, for any $s \geq t_1 n^{b_0}$, the distance between times $s - 1$ and s varies by an increment of $\Delta_{ij}(s)$, where, by (35),

$$\begin{aligned} \Delta_{ij}(s) &= \left| \|x_i(s) - x_j(s)\|_2 - \|x_i(s-1) - x_j(s-1)\|_2 \right| \\ &\leq \left\| \sum_k \Psi_k \mu_k^{s-1-t_1} \right\|_2 + \left\| \sum_k \Psi_k \mu_k^{s-t_1} \right\|_2 \\ &\leq e^{-(s-t_1)n^{-O(1)} + O(\mathfrak{p})} \leq e^{-t_1 n^2}. \end{aligned}$$

With n assumed large enough, this ensures that, past time $t_1 n^{b_0}$, the distance can never cross the value 1. Thus, if the two birds have not gotten within distance 1 of each other by time $t_1 n^{b_0}$, they never will—at least while their respective flocks remain invariant. We conclude that $t \leq t_1 n^{O(1)}$.

Case III. $B = 0$ and $\|A\|_2 = 1$: The distance between the two birds tends toward 1. The concern is that the two birds might stay safely away from each

other for a long period of time and then suddenly decide to get close enough to share an edge. The rationality of the limit configuration is insufficient to prevent this. Only a local analysis of the convergence can show that a long-delayed pairing is impossible. We wish to prove that, if $\text{DIST}_s(\mathcal{B}_i, \mathcal{B}_j)$ is to fall below 1 for $s > t_1$, this must happen relatively soon. Recall that, by (34),

$$x_i(s) - x_j(s) = A - \sum_{k=1}^{m_0} \Psi_k \mu_k^{s-t_1},$$

where A is a unit vector. We investigate the behavior of the birds' distance locally around 1.

$$\|x_i(s) - x_j(s)\|_2^2 = 1 - 2 \sum_k A^T \Psi_k \mu_k^{s-t_1} + \sum_{k,k'} \Psi_k^T \Psi_{k'} (\mu_k \mu_{k'})^{s-t_1}.$$

Let $1 > \rho_1 > \dots > \rho_N > 0$ be the distinct nonzero values among $\{|\mu_k|, |\mu_k \mu_{k'}|\}$ ($N < n^2$). These absolute values may appear with a plus or minus sign (or both) in the expression above, so we rewrite it as

$$\|x_i(s) - x_j(s)\|_2^2 - 1 = \sum_{k=1}^N \Upsilon_k \rho_k^{s-t_1}, \quad (36)$$

where each

$$\Upsilon_k = \Upsilon_k^+ + (-1)^s \Upsilon_k^-$$

corresponds to a distinct ρ_k . We distinguish between odd and even values of s so as to keep each Υ_k time-invariant. We assume that s is even and skip the odd case because it is similar. Of course, we may also assume that each $\Upsilon_k = \Upsilon_k^+ + \Upsilon_k^-$ is nonzero. We know that $\sum_k \Upsilon_k \rho_k^{s-t_1}$ tends to 0 as s goes to infinity, but the issue is how so. To answer this question, we need bounds on eigenvalue gaps and on $|\Upsilon_k|$. Tighter results could be obtained from current spectral technology, but they would not make any difference for our purposes, so we settle for simple, conservative estimates.

LEMMA 3.23. *For all $k > 1$ and $k \geq 1$, respectively,*

$$\rho_k \leq (1 - 2^{-n^{O(1)}}) \rho_1 \quad \text{and} \quad 2^{-t_1 2^{n^{O(1)}}} \leq |\Upsilon_k| = 2^{O(\mathfrak{p})}.$$

Proof. We begin with the eigenvalue gap.¹⁰ For this we use a conservative version of Canny's root separation bound [2, 30]: given a system of m integer-coefficient polynomials in m variables with a finite set of complex solution points, any nonzero coordinate has modulus at least

$$2^{-\ell D^{O(m)}}, \quad (37)$$

¹⁰ For the purpose of this lemma, we again abuse notation by letting P and n pertain to the flock of either one of the two birds. This will help the reader keep track of the notation while, as a bonus, releasing m as a variable.

where $D - 1$ is the maximum degree of any polynomial and ℓ is the number of bits needed to represent any coefficient. Any difference $\rho_k - \rho_l$ can be expressed by a quadratic polynomial, $z = z_1 z_2 - z_3 z_4$, where each z_i is either 1 or the root of the characteristic polynomial $\det(P - \lambda I_n)$. The elements of P are CD-rationals over $O(n \log n)$ bits, so by the Hadamard bound [30] the roots of $\det(P - \lambda I_n)$ are also those of a polynomial of degree n with integer coefficients over $O(n^2 \log n)$ bits; therefore, $m \leq 5$; $D = n + 1$; and $\ell = n^{O(1)}$. This proves that the minimum gap between two ρ_k 's is $2^{-n^{O(1)}}$. Since $\rho_1 < 1$, we find that, for $k > 1$,

$$\rho_k \leq (1 - 2^{-n^{O(1)}})\rho_1,$$

which proves the first part of the lemma.

By (iv), $\|\Psi_l\|_2 = 2^{O(\mathfrak{p})}$; therefore, by Cauchy-Schwarz and the inequalities $\rho_k < 1$ and $\mathfrak{p} \geq n^3$, the same bound of $2^{O(\mathfrak{p})}$ applies to any $|\Upsilon_k|$, which proves the second upper bound of the lemma. We now prove that $|\Upsilon_k|$ cannot be too small. Recall that it is the sum/difference of inner products between vectors in $\{A, \Psi_h\}$. We know from (iv) that Ψ_h is of the form $\Phi_l/(1 - \lambda_l)$ or $-\Phi'_l/(1 - \lambda'_l)$. We assume the former without loss of generality. By (9, 12),

$$\Gamma = \sum_{r=2}^n \sum_{s \geq 0} \lambda_r^s C^{1/2} u_r u_r^T C^{-1/2}.$$

In view of (iv) and (33), it then follows that

$$\begin{aligned} \Psi_h &= \frac{\Phi_l}{1 - \lambda_l} = \frac{1}{1 - \lambda_l} \left\{ (\chi(i)^T C^{1/2} u_l u_l^T C^{-1/2}) \otimes I_d \right\} v(t_1 + 1) \\ &= \frac{1}{1 - \lambda_l} \left\{ (\chi(i)^T C^{1/2} u_l u_l^T C^{-1/2} C^{1/2} u_l u_l^T C^{-1/2}) \otimes I_d \right\} v(t_1 + 1) \\ &= \sum_{r=2}^n \frac{1}{1 - \lambda_r} \left\{ (\chi(i)^T C^{1/2} u_r u_r^T C^{-1/2} C^{1/2} u_l u_l^T C^{-1/2}) \otimes I_d \right\} v(t_1 + 1) \\ &= \sum_{r=2}^n \sum_{s \geq 0} \left\{ (\chi(i)^T \lambda_r^s C^{1/2} u_r u_r^T C^{-1/2} C^{1/2} u_l u_l^T C^{-1/2}) \otimes I_d \right\} v(t_1 + 1) \\ &= ((\chi(i)^T \Gamma C^{1/2} u_l u_l^T C^{-1/2}) \otimes I_d) v(t_1 + 1) = ((\chi(i)^T \Gamma) \otimes I_d) W, \end{aligned}$$

where $W = ((C^{1/2} u_l u_l^T C^{-1/2}) \otimes I_d) v(t_1 + 1)$. By Lemma 3.2, $v(t_1 + 1)$ is a vector with CD-rational coordinates over $O(t_1 n \log n)$ bits; remember that $t_1 > \mathfrak{p}$. By Lemma 3.12, the elements of Γ are CD-rationals encoded over $O(n \log n)$ bits. Any coordinate of Ψ_h can thus be written as a sum \sum_i of at most n^2 terms of the form $R_i \alpha_i y_i z_i$, where:

- All the R_i 's are products of the form $\Gamma_{**} v_*(t_1 + 1)$, hence CD-rationals over $O(t_1 n \log n)$ bits;

- α_i is the square root of a rational c_\star/c_\star over $O(\log n)$ bits;
- y_i, z_i are two coordinates of u_l . Recall that, by (8), u_l is a unit eigenvector of $C^{-1/2}PC^{1/2}$.

By (i), A is a vector with CD-rational coordinates over $O(t_1 n \log n)$ bits. It follows that Υ_k is a sum \sum_i of $n^{O(1)}$ terms of the form $S_i \gamma_i y_i z_i y'_i z'_i$:

- All the S_i 's are CD-rationals over $O(t_1 n \log n)$ bits;
- γ_i is the square root of an $O(\log n)$ -bit rational, ie, a number of the form $\sqrt{(c_\star/c_\star)(c_\star/c_\star)}$;
- y_i, z_i, y'_i, z'_i are coordinates of the eigenvectors (or 1, to account for $A^T \Psi_h$).

It is straightforward (but tedious) to set up an integer-coefficient algebraic system over $m = n^{O(1)}$ variables that includes Υ_k as one of the variables. The number of equations is also m and the maximum degree is n . All the coefficients are integers over $O(t_1 n \log n + n^{O(1)})$ bits. Rather than setting up the system in full, let us briefly review what it needs to contain:

1. Υ_k is a sum of $n^{O(1)}$ quintic monomials $S_i \gamma_i y_i z_i y'_i z'_i$; where the S_i 's are CD-rationals over $O(t_1 n \log n)$ bits.
2. Each γ_i is of the form $\sqrt{a/b}$, where a, b are $O(\log n)$ -bit integers. We express it by the equation $b\gamma_i^2 = a$. (This yields two roots, but any solution set is fine as long as it is finite and contains those we want.)
3. The y_i, z_i, y'_i, z'_i are coordinates of the eigenvectors u_l of $C^{-1/2}PC^{1/2}$. We specify them by first defining the eigenvalues $\lambda_1, \dots, \lambda_n$ and

$$\begin{cases} \det(P - \lambda_i I_n) = 0; \\ C^{-1/2}PC^{1/2}u_i = \lambda_i u_i; & (1 \leq i < j \leq n) \\ \|u_i\|_2^2 = 1, \text{ and } u_i^T u_j = 0. \end{cases}$$

The issue of multiplicity arises. If the kernels of the various $P - \lambda_i I_n$ are not of dimension 1, we must throw in cutting planes to bring down their sizes. We add in coordinate hyperplanes to the mix until we get the right dimension. We then repeat this process for each multiple eigenvalue in turn. (Of course, we do all this prior to forming the vectors Ψ_h .) We rewrite each eigensystem as $Pv_i = \lambda_i v_i$, where $v_i = C^{1/2}u_i$, and again we square the latter set of equations to bring them in polynomial form.

Once we reduce all the rational coefficients to integers, we can use the separation bound (37), for $m = n^{O(1)}$, $D = n + 1$, and $\ell = O(t_1 n \log n + n^{O(1)})$, which is $O(t_1 n \log n)$. This gives us a bound on the modulus of any nonzero coordinate of the solution set; hence on $|\Upsilon_k|$. \square

By (36), it follows from the lemma that $\|x_i(s) - x_j(s)\|_2^2 - 1 = \Upsilon_1 \rho_1^{s-t_1}(1 + \zeta)$, where

$$|\zeta| \leq e^{-(s-t_1)2^{-n}O(1) + t_1 2^n O(1)} = o(1),$$

for $s \geq t_1 2^{n^{b_1}}$, with b_1 being a large enough constant. The same argument for odd values of s shows that, after $t_1 2^{n^{b_1}}$, either $\|x_i(s) - x_j(s)\|_2^2$ stays on one side of 1 forever or it constantly alternates (at odd and even times). Since the birds are joined in G_t but not in G_s ($t_1 \leq s < t$), it must be the case that $t \leq t_1 2^{n^{O(1)}}$. This concludes Case III.

Putting all three results together, we find that the bound from Case I is the most severe, $t \leq n^{O(t_1^n)}$, while Case II is the most lenient. When the two birds are in the same flock at time $t-1$, however, the bound from Case III takes precedence. \square

Lemmas 3.21 and 3.22 show that all network switches take place within the first $t_\infty = 2 \uparrow\uparrow O(n)$ steps. Perturbations occur within $n^{O(1)}$ steps of a switch and do not affect Lemma 3.2. The previous argument thus still applies and shows that the same upper bound also holds in the noisy model. After time t_∞ , the flocking network remains invariant. By virtue of (18), the limit trajectory of the birds within a given flock is expressed as

$$x(t) = x^r + ((\mathbf{1}\pi^T) \otimes I_d)x(t_\infty) + (t - t_\infty)((\mathbf{1}\pi^T) \otimes I_d)v(t_\infty + 1),$$

where the stationary distribution π refers to the bird's flock (and therefore should be annotated accordingly).

3.4 Tower of Logarithmic Height

We prove that the tower-of-twos has height less than $4 \log n$. To simplify the notation (a decision whose wisdom the reader will soon come to appreciate), we now adopt the assumptions of (2). As we discussed earlier, this means setting the fragmentation breakpoint $t_f = n^{f_0 n^3}$ for some large enough constant f_0 . The improvement rests on a more careful analysis of the merges subsequent to the fragmentation breakpoint t_f . Note that in the proof of Lemma 3.22 the bottleneck lies in Case I: specifically, in the lower bound on $\|B\|_2$ and the upper bound on $\|A\|_2$. The latter can be improved easily by invoking the Escape Lemma. To get around $\|B\|_2$ requires more work. Recall from (17) that the position vector of one flock is given by

$$x(t) = a + bt + (\Gamma_t \otimes I_d)v,$$

where the matrix Γ_t describes a damped oscillator. The stationary velocity b is formed by the first spectral coordinates, one for each dimension, associated with the eigenvalue 1. The oscillator involves only the spectral coordinates corresponding to the subdominant eigenvalues ($|\lambda_k| < 1$).

The Combinatorics of the Spectral Shift. The reason flocks take longer to merge into larger flocks is that they fly in formations increasingly parallel to one another. The term bt grows linearly in t , so an iterated exponential growth can only come from the oscillator. Of course, the angle between the flight directions of two flocks is given by the stationary velocities. Therefore, for the angles to inherit an exponentially decaying growth, it is necessary to *transfer* the fast-decaying energy of the oscillators to the stationary velocities themselves. In other words, the collision between two flocks must witness a spectral shift from the “subdominant” eigenspace to the stationary velocities. Small angles are achieved by getting two stationary velocities to be very close to each other. Indeed, the spectral shift does not cause a decay of the velocities themselves but of pairwise differences. Recall that flocking is invariant under translation in velocity space; so any interesting phenomenon can be captured only by differences.

Let b be the stationary velocity of the new flock formed by two flocks joining together after flying on their own during t steps. Let b' be the stationary velocity resulting from two other flocks flying in similar conditions. The spectral shift will ensure that the difference $b - b'$ has Euclidean norm $e^{-tn^{-O(1)}}$, ie, exponentially small in the flight time. One should think of it as an energy transfer from the subdominant eigenspaces to the stationary velocities. The challenge is to show that this transfer can occur only under certain conditions that greatly restrict its occurrence. This requires a combinatorial investigation of the spectral shift.

Figure 18: Without spectral shift, the difference between stationary velocities becomes null and the two flocks never meet. The spectral shift resupplies the stationary velocities with the fast-decaying energy located in the subdominant part of the spectrum. This causes a slight inflection of the trajectory (black lines).

We model the sequence of post-fragmentation breakpoint merges by a forest \mathcal{F} : each internal node a corresponds to a flock F_a of n_a birds formed at time $t_a > t_f$. If a is a leaf of \mathcal{F} , then its formation time t_a is at most t_f . A node with at least two children is called *branching*. A nonbranching node represents the addition of edges within the same flock. Our analysis will focus on branching nodes with no more than two children. In general, of course, this number can be arbitrarily high, as several flocks may come together to merge simultaneously. We will see later how to break down multiple aggregation of this form into pairwise merges.

Let $L(t)$ denote the minimum value of n_a , the number of birds in F_a , over all branching nodes a and all initial conditions subject to (2), such that $t_a \geq t$. Our previous upper bound shows that $L(t) = \Omega(\log^* t)$. We strengthen this:

LEMMA 3.24. $L(t) \geq (1.1938)^{\log^* t - O(\log \log n)}$, where $x_0 \approx 1.1938$ is the unique real root of $x^5 - x^2 - 1$.

This implies that the last merge must take place before time t such that $L(t) \leq n$; hence $t \leq 2 \uparrow \uparrow (3.912 \log n)$. By Lemma 3.22, multiplying this quantity by $2^{n^{O(1)}}$ suffices to account for the network switches following the last merge. As observed earlier, noise has no effect on this bound. This proves the upper bound claimed in §1. \square

The Intuition. Think of the group of birds as a big-number engine. How many bits can n birds encode in their velocities at the last network switch? The previous argument shows that this number cannot exceed a tower-of-twos of linear height. We show that in fact the height is only logarithmic. What keeps this number down is the presence of *residues*. We begin with a toy problem that has no direct connection to bird flocking but illustrates the notion of residue. Consider an n -leaf binary tree whose nodes are associated with polynomials in $\mathbb{R}[X]$. Each leaf is assigned its own polynomial of degree 1. The polynomial p_v at an internal node v is defined recursively by combining those at the children u, w :

$$p_v = p_u \oplus p_w = p_u + p_w + (p_u - p_w)x^{2^{h(p_u - p_w)}},$$

where $h(p)$ is 0 if $x = 0$ not a root of p and $h(p)$ is its multiplicity otherwise; in other words, it is the lowest degree among the (nonzero) monomials of p . How big can the degree of p_{root} be? It is immediate to achieve a degree that is a tower-of-twos of logarithmic height. Take a complete binary tree and assign the polynomial $(-1)^{l(v)}x$ to a leaf v , where $l(v)$ is the number of left turns from the root to the leaf. We verify by induction that the polynomials at level k are of the form $\pm c_k x^{d_k}$, where $d_1 = 1$ and, for $k > 1$,

$$c_k x^{d_k} = \pm 2c_{k-1} x^{d_{k-1} + 2^{d_{k-1}}}.$$

This shows that $d_k = d_{k-1} + 2^{d_{k-1}}$; hence the stated tower-of-twos of logarithmic height. Couldn't we increase the height by choosing a nonbalanced tree? The

answer is no, but not for the obvious reason. The “obvious reason” would be that to go from a node u of degree d to a parent of degree 2^d requires not just one but two children u, v of degree d . Nice idea. Unfortunately, it is not true:

$$x^d \oplus 0 = x^d + x^{d+2^d}. \quad (38)$$

Note, however, that if we try to repeat this trick we get

$$(x^d + x^{d+2^d}) \oplus 0 = x^d (1 + x^{2^d})^2,$$

which increases the degree by only a constant factor. The reason for this is that during the exponential jump in (38) the polynomial inherited a *residue*, ie, the “low-degree” monomial x^d , which will hamper future growth until it is removed. But to do so requires another “big-degree” child. This residue-clearing task is what keeps the tower’s height logarithmic. We prove this below.

THEOREM 3.25. *A tree of n nodes can produce only polynomials of degree at most $2 \uparrow \uparrow O(\log n)$.*

Proof. Let $L(d)$ be the minimum number of leaves needed to produce at the root a polynomial of degree at least d . We prove that

$$L(d) \geq 2^{\Omega(\log^* d)}, \quad (39)$$

from which the theorem follows. Let v be the root of the smallest n -leaf tree that achieves $d_v \geq d$, where d_v denotes the degree of p_v . Let u, w be the children of v , with $d_u \geq d_w$, and let y, z be the children of u with $d_y \geq d_z$. We assume that d is large enough, so all these nodes exist. Note that

$$d_v \leq d_u + 2^{d_u} \quad \text{and} \quad d_u \leq d_y + 2^{d_y}. \quad (40)$$

Assume that

$$\begin{cases} d_z, d_w < \log \log \log d_v; \\ d_y < \sqrt{d_u} < d_u < \sqrt{d_v}. \end{cases} \quad (41)$$

In view of (40), this shows that $d_u > d_w$ and $d_y > d_z$. This first inequality implies that $d_u + 2^{h(p_u - p_w)} = d$; therefore, by (41), $h(p_u - p_w) > \frac{1}{2} \log d_v$. In other words,

$$p_u = p_w + x^{\lceil (\log d_v)/2 \rceil} q_u, \quad (42)$$

for some polynomial $q_u \neq 0$. Repeating the same line of reasoning at node u , we derive the identity $d_y + 2^{h(p_y - p_z)} = d_u$ from the strict inequality $d_y > d_z$. It follows from (40, 41) that

$$d_z < \log \log \log d_v < \frac{1}{2} \log d_u < h(p_y - p_z) \leq \log d_u < \frac{1}{2} \log d_v.$$

This implies two things: first, by $d_z < h(p_y - p_z)$, the polynomial p_y has a monomial q of degree $h(p_y - p_z)$; second, that degree is strictly between $\log \log \log d_v$ and $\frac{1}{2} \log d_v$. A quick look at the formula

$$p_u = p_y + p_z + (p_y - p_z)x^{2^{h(p_y - p_z)}}$$

shows that p_u also contains q : indeed, by $d_z < h(p_y - p_z)$, it must be the case that $p_y + p_z$ contains the monomial q ; on the other hand, the minimum degree in $(p_y - p_z)x^{2^{h(p_y - p_z)}}$ exceeds $h(p_y - p_z)$. This proves the presence of q in p_u , which contradicts (42). This, in turn, means that (41) cannot hold. The monomial q of degree $h(p_y - p_z)$ is the *residue* that the big-number engine must clear before it can continue exponentiating degrees. Since $d_y > \frac{1}{2} \log \log d$, at least one of these two conditions applies for any large enough d :

$$L(d) \geq \begin{cases} L(\frac{1}{2} \log \log d) + L(\log \log \log d); \\ L(d^{1/4}) + 1. \end{cases}$$

We use the monotonicity of L to reduce all the cases to the two above. The lower bound (39) follows by induction. \square

Clearing Residues. Recall that $t_a > t_f$ is the time at which the flock F_a is formed at node a of \mathcal{F} after the fragmentation breakpoint $t_f = n^{f_0 n^3}$. With the usual notational convention, it follows from (1, 9) that, in the absence of noise, for $t \geq t_a$,

$$\begin{aligned} v_a(t) &= (P^{t-t_a} \otimes I_d)v_a(t_a) \\ &= (\mathbf{1}_{n_a} \otimes I_d)\mathbf{m}_a + \sum_{k>1} \lambda_k^{t-t_a} ((C^{1/2}u_k u_k^T C^{-1/2}) \otimes I_d)v_a(t_a), \end{aligned}$$

where $\mathbf{m}_a = (\pi_a^T \otimes I_d)v_a(t_a)$ is the stationary velocity of the flock F_a , ie, the d -dimensional vector of first spectral coordinates. As usual, it is understood that P, C, λ_k, u_k , etc, are all defined with respect to the specific flock F_a and not the whole group of n birds. We subscript $\mathbf{1}$ with the flock size for convenience. By (2), $\mathfrak{p} = n^3$; hence, by (3, 10),

$$\|v_a(t) - (\mathbf{1}_{n_a} \otimes I_d)\mathbf{m}_a\|_2 \leq e^{-(t-t_a)n^{-O(1)+O(n^3)}}. \quad (43)$$

By the general form of the stationary distribution π_a as $(\text{tr } C^{-1})^{-1}C^{-1}\mathbf{1}_{n_a}$, its coordinates are CD-rationals over $O(n \log n)$ bits. So, by Lemma 3.2, each coordinate of \mathbf{m}_a is an irreducible CD-rational p_a/q_a , where the number of bits needed for p_a and q_a is $O(t_a n \log n + \mathfrak{p}n) = O(t_a n \log n)$. We denote the maximum bit length over all d coordinates by $\ell(\mathbf{m}_a)$. The following holds even in the noisy model:

$$\ell(\mathbf{m}_a) = O(t_a n \log n). \quad (44)$$

Consider a flock F_c associated with a branching node c of \mathcal{F} : let a and b be the two children of c in \mathcal{F} (hence $n_c = n_a + n_b$) and assume that $t_a \geq t_b$ and that no node of the forest \mathcal{F} has more than two children, ie, flocks merge only two at a time.¹¹ By Corollary 3.20, the difference in stationary velocities between F_a and F_b satisfies

$$\|\mathbf{m}_a - \mathbf{m}_b\|_2 \leq \frac{\log t_c}{t_c} n^{O(n^3)}. \quad (45)$$

If the difference is null, then by Cases II, III of the previous analysis ($B = 0$), $t_c = t_a 2^{n^{O(1)}}$. Otherwise, by (44) and the equivalent bound for $\|\mathbf{m}_b\|_2$,

$$\|\mathbf{m}_a - \mathbf{m}_b\|_2 \geq n^{-O(t_a n)}. \quad (46)$$

The two inequalities (45, 46) yield an upper bound on t_c . By our treatment of Cases II, III in the proof of Lemma 3.22, we conclude that, whether $\mathbf{m}_a = \mathbf{m}_b$ or not,

$$t_c \leq n^{O(t_a n)}. \quad (47)$$

This leads to our earlier $\Omega(\log^* t)$ bound on $L(t)$. It is essentially a new derivation of our previous result. We now see how to improve it. Let \mathcal{F}_o be the forest derived from \mathcal{F} by removing all nonbranching internal nodes and merging the adjacent edges in the obvious way. Our assumption implies that each internal node of \mathcal{F}_o has exactly two children. Let a_0, \dots, a_k ($k > 1$) be an ascending path in \mathcal{F}_o and let b_i denote the unique sibling of a_i . The following lemma assumes the noisy model. Its proof is postponed.

LEMMA 3.26. *Assume that $2^{2^{t_f}} < \log \log \log t_{a_k} < t_{a_0}^4 < t_{a_1} < \log t_{a_k}$. Then, $t_{b_{i_0}} \geq \sqrt{\log \log t_{a_0}}$, for some $0 \leq i_0 < k$.*

The Recurrence. We set up a recurrence relation on $L(t)$ to prove the lower bound of Lemma 3.24, ie, $L(t) \geq (1.1938)^{\log^* t - O(\log \log n)}$. Let $t_0 = 2 \uparrow \uparrow \lfloor \log \log n \rfloor$. It is assumed as usual that n is large enough. For $t \leq t_0$, we have the trivial lower bound $L(t) \geq 1$ (choose the constant in the big-oh to be larger than 1), so we may assume that $t > t_0$. The child b of a node c (both defined with respect to \mathcal{F}_o) is called *near* if $t_b > (\log t_c)^{2/3}$.

¹¹ The simultaneous merging of more than two flocks can be dealt with by breaking ties arbitrarily. Since there are fewer than n merges, this means that in our calculations time might be off by at most an additive term less than n . One can verify that this discrepancy has no real effect on any of the derivations and conclusions presented below.

Figure 19: A big flock F_a may join with a small one, F_b , to form a flock F_c that produces a much larger number than either one could manufacture on their own. This, however, cannot be repeated in the next step. To create a bigger number at the parent flock of F_c , the residual heat in F_c (numbers in box) must be evacuated, which itself requires free energy that can only be provided by a flock F_d that roughly matches F_c in size. In this way, an abundance of spectral shifts forces balance into the forest \mathcal{F} .

LEMMA 3.27. *Any internal node c of \mathcal{F}_o such that $t_c \geq 2^{2^{t_f}}$ has at least one near child.*

Proof. By (47), we know that c has a child b_0 in the original forest \mathcal{F} such that $t_c = n^{O(t_{b_0})}$. We exhibit a near child b for c . If b_0 is branching, set $b = b_0$; otherwise, set b to the nearest branching descendent of b_0 . By Lemma 3.22, the formation times of any node in \mathcal{F} and its nonbranching parent differ by at most a factor of $2^{n^{O(1)}}$. Perturbations make no difference since they occur within polynomial time of a switch. Since \mathcal{F} has fewer than n^2 nodes and $t_c \geq 2^{2^{t_f}}$, with $t_f = n^{f_0 n^3}$,

$$t_b \geq 2^{-n^{O(1)}} t_{b_0} \geq 2^{-n^{O(1)}} \log t_c > (\log t_c)^{2/3}.$$

□

Let c_0 be an arbitrary node of \mathcal{F}_o such that

$$t_{c_0} \geq t > t_0 = 2 \uparrow \uparrow [\log \log n]. \quad (48)$$

By the previous lemma, we can follow a descending path in \mathcal{F}_o of near children c_0, c_1, \dots, c_l , where $t_{c_l} < 2^{2^{t_f}} \leq t_{c_{l+1}}$. Because t_0 is so much greater than t_{c_l} , the path has more than a constant number of nodes—in fact, at least on the order of $\log \log n$. For future use, we note that

$$2^{2^{t_f}} < \log \log \log t_{c_0}. \quad (49)$$

LEMMA 3.28. *There exists $k > 1$ such that*

$$\log \log \log t_{c_0} < t_{c_k}^4 < t_{c_{k-1}} < \log t_{c_0}.$$

Proof. By (49) and Lemma 3.27, there exists some c_j in \mathcal{F}_o such that

$$(\log \log t_{c_0})^{2/3} < t_{c_j} < \log t_{c_0}.$$

Suppose now that all the nodes c_i , for $i = j + 1, j + 2, \dots, l$, satisfy $t_{c_i}^4 \geq t_{c_{i-1}}$. Since there are most n nodes along the path from c_0 to c_l in \mathcal{F}_o , then, by (49) again,

$$2^{2^{t_f}} > t_{c_l} \geq t_{c_j}^{4^{-n}} > (\log \log t_{c_0})^{4^{-n-1}} > 2^{2^{t_f/2}}. \quad (50)$$

This contradiction proves the existence of some node c_k ($j < k \leq l$) such that

$$t_{c_k}^4 < t_{c_{k-1}} < \log t_{c_0}.$$

The argument used in (50) shows that the smallest such k satisfies, via (49),

$$t_{c_{k-1}} \geq t_{c_j}^{4^{-n}} > (\log \log t_{c_0})^{4^{-n-1}} > 2^{2^{t_f}}.$$

Another application of the inequality above, $t_{c_{k-1}} > 2^{2^{t_f}}$, allows us to invoke Lemma 3.27. By virtue of t_{c_0} being so big (49) and c_k being a near child of c_{k-1} (by construction),

$$t_{c_k}^4 > (\log t_{c_{k-1}})^{8/3} > 4^{-8n} (\log \log t_{c_0})^{8/3} > \log \log \log t_{c_0}.$$

□

We now prove Lemma 3.24. Setting $a_i = c_{k-i}$ for $i = 0, \dots, k$, together with (49), the lemma sets the conditions of Lemma 3.26. This shows that $t_{a_0} > (\log \log \log t_{a_k})^{1/4}$ and, conservatively,

$$t_{b_{i_0}} > (\log \log \log \log t_{a_k})^{1/3}.$$

Nodes a_0 and b_{i_0} are roots of disjoint subtrees, so the number of leaves below a_k is at least that of those below a_0 added to those below b_{i_0} . Since L is a monotone function and, by (48), a_k is an arbitrary node such that $t_{a_k} \geq t$,

$$L(t) \geq L((\log \log \log t)^{1/4}) + L((\log \log \log \log t)^{1/3}),$$

for $t > t_0 = 2 \uparrow \uparrow \lceil \log \log n \rceil$, and $L(t) \geq 1$ for $t \leq t_0$. We solve the recurrence without the exponents, and then show that ignoring them makes no asymptotic difference. Define $L^*(t) = 1$ for $t \leq t_0$ and, for any $t > t_0$,

$$L^*(t) = L^*(\log \log \log t) + L^*(\log \log \log \log t).$$

Given the bound we are aiming for, we can round off t down to the next tower-of-twos. If $L^*(t) = M(\sigma)$, where $\sigma = \log^* t$, we can rewrite the recurrence relation as

$$M(\sigma) = M(\sigma - 3) + M(\sigma - 5),$$

where $M(\sigma) = 1$ for $\sigma \leq \log^* t_0$. Quite clearly, $M(\sigma)$ upper-bounds the maximum number n_s of leaves in a binary tree \mathcal{T}^* where: (i) each left edge is labeled 3 and each right edge 5; and (ii) the sum of the labels along any path is at most $s = \log^* t - \log^* t_0$. Note that \mathcal{T}^* is binary: the constraint that each internal node should have exactly two nodes does not follow from the definition and is therefore added. We seek a lower bound of the form cx^s . This means that $x^s \geq x^{s-3} + x^{s-5}$, for $s \geq 5$ and $cx^s \leq 1$ else. The characteristic equation is

$$x^5 - x^2 - 1 = 0.$$

We choose the unique real root $x_0 \approx 1.19385$; this leads to $c = x_0^{-5}$. This shows that $n_s \geq x_0^{s-5}$; hence,

$$L^*(t) \geq x_0^{\log^* t - \log \log n - 5}.$$

It is obvious that the binary tree \mathcal{T} associated with the recurrence for $L(t)$ embeds in \mathcal{T}^* with the same root. We claim that it is not much smaller: specifically, no leaf in \mathcal{T} has more than a constant number of descendants in \mathcal{T}^* . This implies immediately that

$$L(t) \geq x_0^{\log^* t - O(\log \log n)},$$

which proves Lemma 3.24. □

To prove our claim, we show that no path in \mathcal{T}^* extends past its counterpart in \mathcal{T} by more than a constant number of nodes. We model simultaneous, parallel walks down the trees as a collaborative game between two players, Bob and Alice, who take turns. Initially, both of them share the same value

$$t_A = t_B = t > t_0.$$

In one round, Bob modifies his current value by taking iterated logs. He is entitled to up to 5 logarithm iterations; in other words, he can set $t_B \leftarrow \log t_B$ or

$$t_B \leftarrow \log \log \log \log \log t_B,$$

or anything in-between. Alice mimics Bob's move but then completes it by taking a fractional power; for example, if Bob opts for, say, $\log \log t_B$, then Alice resets her value to $(\log \log t_A)^\alpha$, where α is a number between $\frac{1}{4}$ and 1. To summarize, Bob chooses the number of log iterations and Alice chooses α : they can change these parameters at each round. A player's *score* is the number of rounds before his or her value falls below (or at) t_0 . Alice's score cannot be higher than Bob's, so the latter is expected to play the last rounds on his own.

The joint goal of the players is to maximize their score differential. Regardless of either player's strategy, we show that Bob's score never exceeds Alice's by more than a constant. This follows directly from the next two lemmas, whose proofs we postpone.

LEMMA 3.29. *The score differential is maximized when Bob always selects the single-iterated log rule and Alice follows suit with $\alpha = \frac{1}{4}$; in other words, $t_B \leftarrow \log t_B$ and $t_A \leftarrow (\log t_A)^{1/4}$.*

With the strategy of the lemma, Bob's score is $\log^* t - \log^* t_0$. Within an additive constant, Alice's score is at least the minimum h such that $c_h \geq t$, where c_i is defined by $c_0 = t_0^4$ and, for $i > 0$, $c_i = 2^{4c_{i-1}}$. To see why, note that the inverse of the function $z \mapsto (\log z)^{1/4}$ is $z \mapsto 2^{z^4}$; taking logarithms on both sides gives the recurrence on c_i .

LEMMA 3.30. *For $t > t_0$, $\min\{h \mid c_h \geq t\} \geq \log^* t - \log^* t_0 - O(1)$.*

This validates our claim that no path in \mathcal{T}^* extends past its counterpart in \mathcal{T} by more than a constant number of nodes. This fills in the missing part in the proof of Lemma 3.24 and establishes the upper bound on the convergence time claimed in §1.

Proof of Lemma 3.26. We begin with a few technical facts. Recall from the ‘‘Clearing Residues’’ section that the flock F_c is associated with a branching node c of \mathcal{F} and that a and b are its two children in \mathcal{F} ; furthermore, $t_a \geq t_b$ and $t_a > t_f$, where $t_f = n^{f_0 n^3}$. Assume that the velocity vector of F_a at time t_a is of the form

$$v_a(t_a) = (\mathbf{1}_{n_a} \otimes I_d) \tilde{\mathbf{m}}_a + (u_a \otimes I_d) \mu_a + \zeta_a, \quad (51)$$

where $u_a \in \mathbb{R}^{n_a}$, $\mu_a \in \mathbb{R}^d$, and, for some real τ ,

$$\begin{cases} 2^{t_f} \leq \tau \leq t_a^{1/3}; \\ \ell(\tilde{\mathbf{m}}_a) = O(\log \log \tau); \\ \|u_a\|_\infty = 1 \ \& \ u_a \geq 0; \\ e^{-\tau n^{O(1)}} \leq \|\mu_a\|_2 \leq \frac{1}{\tau}; \\ \|\zeta_a\|_2 \leq e^{-\tau^2 n^{-O(1)} + n^{O(1)}}. \end{cases} \quad (52)$$

Note that the d -dimensional rational vector $\tilde{\mathbf{m}}_a$ is not defined as the stationary velocity \mathbf{m}_a of F_a , though it plays essentially the same role. The term $(u_a \otimes I_d) \mu_a$ creates the *residue* $\|\mu_a\|_2$ of F_a . Unless F_b can ‘‘destroy’’ this residue when it joins with F_a , one should not expect the flock formation time to grow exponentially. The crux is then to show that only a flock F_b with many birds can perform such a task. The following result says that, if the flock F_b settles too early, its effect on the residue of F_a is negligible. The conditions on F_c stated below differ slightly

from those for F_a to make them closed under composition. The lemma below also covers the case $n_b = 0$, when the transition from F_a to F_c involves the addition of an edge within the same flock. (Here, too, we assume without loss of generality that these additions occur only one at a time within the same flock.) We postpone the proof of this result.

LEMMA 3.31. *Suppose that F_a undergoes no perturbation. If node b is well defined, then assume that $t_b < \log \log \tau$. Whether node b exists or not,*

$$v_c(t_c) = (\mathbf{1}_{n_c} \otimes I_d)\tilde{\mathbf{m}}_a + (u_c \otimes I_d)\mu_c + \zeta_c,$$

where

$$\begin{cases} \|u_c\|_\infty = 1 \ \& \ u_c \geq 0; \\ \|\mu_a\|_2 n^{-O(1)} \leq \|\mu_c\|_2 \leq \|\mu_a\|_2; \\ \|\zeta_c\|_2 \leq n\|\zeta_a\|_2 + e^{-\tau^2}. \end{cases}$$

Furthermore, if node b is well defined, then $\mathbf{m}_b = \tilde{\mathbf{m}}_a \neq \mathbf{m}_a$.

Remark 2.3. It might be helpful to explain, at an intuitive level, the meaning of the three terms in the expression for $v_a(t_a)$, or equivalently $v_c(t_c)$: $\tilde{\mathbf{m}}_a$ is a low-precision approximation of the stationary velocity \mathbf{m}_a ; the vector $(u_a \otimes I_d)\mu_a$ creates the residue; the remainder ζ_a is an error term. The term $\tilde{\mathbf{m}}_a$ is a low-resolution component of the velocity that any other flock F_b has to share if it is to create small angles with F_a (the key to high flock formation times) Think of it as a shared velocity caused by, say, wind affecting all flocks in the same way. This component must be factored out from the analysis since it cannot play any role in engineering small angles. This is a manifestation of the relativity principle that only velocity *differences* matter. To create small angles with F_a , incoming flocks F_b must attack the residue vector $(u_a \otimes I_d)\mu_a$. Of course, they could potentially take turns doing so. Informally, one should read the inequalities of the lemma as a repeat of (52). The lemma states a closure property: unless F_b brings many bits to the table (via a formation time at least $\log \log \tau$), conditions (52) will still hold. These conditions prevent the creation of small angles between flocks, and hence of huge formation times. In other words, flocks that settle too early cannot hope to dislodge the residue $\|\mu_a\|_2$. The reason is that this residue is shielded in three ways: first, it is too big for the error term ζ_a to interfere with it—compare $e^{-\tau n^{O(1)}}$ with $e^{-\tau^2 n^{-O(1)} + n^{O(1)}}$; second, it is too small to be affected by $\tilde{\mathbf{m}}_a$ —compare $\frac{1}{\tau}$ with a rational over $O(\log \log \tau)$ bits; third, all of its coordinates have the same sign ($u_a \geq 0$), so taking averages among them cannot cause any cancellations. This form of “enduring” positivity is the most remarkable aspect of residues.

By (52), the lemma’s bounds imply that

$$e^{-\tau n^{O(1)}} \leq \|\mu_c\|_2 \leq \frac{1}{\tau} \quad \& \quad \|\zeta_c\|_2 \leq e^{-\tau^2 n^{-O(1)} + n^{O(1)}},$$

which brings us back to (52). If c has a (unperturbed) parent c' and sibling b' , then we can apply the lemma again. Note that composition will always be applied for the same value of τ , ie, one is that is not updated at each iteration. In other words, the first two lines of (52), unlike the last three, are global inequalities that do not change with each iteration. This closure property is not foolproof. First, of course, we need to ensure that $t_{b'} < \log \log \tau$. More important, we lose a polynomial factor at each iteration, which is conveniently hidden in the big-oh notation. So we may compose the lemma only $n^{O(1)}$ times if we are to avoid any visible loss in the bounds of (52). Since the forest has fewer than n^2 nodes, this means that, as long as its conditions are met, we can compose the lemma with ancestors of c to our heart's content and still get the full benefits of (52).

The provision that b might not be well defined allows us to handle nonbranching switch nodes with equal ease. Recall that $v_c(t_c)$ is the velocity leading to time t_c , ie, before the flock F_b has had a chance to influence it. The provision in question might thus appear somewhat vacuous. Its power will come from allowing us to apply the lemma repeatedly with no concern whether a node has one of two children. A related observation is that nowhere shall we use the fact that t_a is the actual formation time of F_a . It could be replaced in (51) by any t'_a strictly between t_a and t_c . We thus trivially derive a “delayed” version of Lemma 3.31. We summarize its two features: (i) Lemma 3.31 can be composed iteratively as often as we need to; (ii) node a need not be an actual node of \mathcal{F} but one introduced artificially along an edge of \mathcal{F} .

What if F_a undergoes a perturbation between t_a and t_c ? Then the flock F_a sees its velocity multiplied by $I_{n_a} \otimes \hat{\alpha}$, where $\hat{\alpha}$ is the diagonal matrix with $\alpha = (\alpha_1, \dots, \alpha_d)$ along the diagonal and rational $|\alpha_i| \leq 1$ encoded over $O(\log n)$ -bits. Observe that the two matrices $P_a \otimes I_d$ and $I_{n_a} \otimes \hat{\alpha}$ commute; therefore the perturbation can be assumed to occur at time t_a . This means that, in lieu of (51), we have, using standard tensor rules,

$$\begin{aligned} v_a(t_a) &= (I_{n_a} \otimes \hat{\alpha})(\mathbf{1}_{n_a} \otimes I_d)\tilde{\mathbf{m}}_a + (I_{n_a} \otimes \hat{\alpha})(u_a \otimes I_d)\mu_a + (I_{n_a} \otimes \hat{\alpha})\zeta_a \\ &= (\mathbf{1}_{n_a} \otimes \hat{\alpha})\tilde{\mathbf{m}}_a + (u_a \otimes \hat{\alpha})\mu_a + (I_{n_a} \otimes \hat{\alpha})\zeta_a. \end{aligned}$$

Bringing it in the format of (51), we find that

$$v_a(t_a) = (\mathbf{1}_{n_a} \otimes I_d)\tilde{\mathbf{m}}_a + (u_a \otimes I_d)\mu_a + \zeta_a,$$

with the new assignments:

$$\left\{ \begin{array}{l} \tilde{\mathbf{m}}_a \leftarrow \hat{\alpha} \tilde{\mathbf{m}}_a; \\ u_a \leftarrow u_a; \\ \mu_a \leftarrow \hat{\alpha} \mu_a; \\ \zeta_a \leftarrow (I_{n_a} \otimes \hat{\alpha})\zeta_a. \end{array} \right.$$

It is immediate that the conditions of (52) still hold: the only difference is that

$$\ell(\tilde{\mathbf{m}}_c) \leq \ell(\tilde{\mathbf{m}}_a) + O(\log n).$$

By (52), $\log \tau \geq t_f = n^{f_0 n^3}$, so $\ell(\tilde{\mathbf{m}}_c)$ stays in $O(\log \log \tau)$ as long as the number of compositions is $O(n^3)$, which it is. We summarize these observations:

LEMMA 3.32. *Let c_0, \dots, c_l be an ascending path in \mathcal{F} and let d_i be the sibling, if any, of c_i . Assume that c_0 , possibly an artificial node, satisfies the conditions of node a in (52) and that $t_{d_i} < \log \log \tau$ for all d_i . Then,*

$$v_{c_i}(t_{c_i}) = (\mathbf{1}_{n_{c_i}} \otimes I_d) \tilde{\mathbf{m}}_{c_i} + (u_{c_i} \otimes I_d) \mu_{c_i} + \zeta_{c_i},$$

where

$$\begin{cases} \ell(\tilde{\mathbf{m}}_{c_i}) = O(\log \log \tau); \\ \|u_{c_i}\|_\infty = 1 \ \& \ u_{c_i} \geq 0; \\ e^{-\tau n^{O(1)}} \leq \|\mu_{c_i}\|_2 \leq \frac{1}{\tau}; \\ \|\zeta_{c_i}\|_2 \leq e^{-\tau^2 n^{-O(1)} + n^{O(1)}}. \end{cases}$$

For all d_i , $\mathbf{m}_{d_i} = \tilde{\mathbf{m}}_{c_i} \neq \mathbf{m}_{c_i}$.

We are now equipped with the tools we need to prove Lemma 3.26. Recall that a_0, \dots, a_k ($k > 1$) is an ascending path in \mathcal{F}_o and b_i denotes the unique sibling of a_i . (Note that $a_0 \cdots a_k$ is a path in \mathcal{F}_o whereas, in Lemma 3.32, $c_0 \cdots c_l$ is a path in \mathcal{F} .) Also,

$$2^{2^{t_f}} < \log \log \log t_{a_k} < t_{a_0}^4 < t_{a_1} < \log t_{a_k}.$$

Assume, by contradiction, that $t_{b_i} < \sqrt{\log \log t_{a_0}}$ for $i = 0, \dots, k-1$. As we observed earlier, Lemma 3.22 ensures that, regardless of noise, the ratio between the formation times of any node in \mathcal{F} and that of its nonbranching parent is at least $2^{-n^{O(1)}}$. Since there are fewer than n^2 switches, this implies that F_{a_0} can undergo switches or perturbations only between t_{a_0} and $t_{a_0} 2^{n^{O(1)}}$. Because $t_{a_1} > t_{a_0}^4 > 2^{2^{t_f}}$, with $t_f = n^{f_0 n^3}$, this shows that the entire time interval $[\frac{1}{2}t_{a_1}, t_{a_1})$ is free of switches and noise. Let a be the last node in \mathcal{F} from a_0 to a_1 and let c_0 be the artificial parent of a corresponding to the flock F_a at time $t_{a_1} - 1$: we set $n_{c_0} = n_{a_0}$ and $t_{c_0} = t_{a_1} - 1$. The bound in (43) ensures that the oscillations in the flock F_{c_0} are heavily damped. Indeed,

$$v_{c_0}(t_{c_0}) = (\mathbf{1}_{n_{c_0}} \otimes I_d) \mathbf{m}_{c_0} + \zeta_{c_0}, \quad (53)$$

where, because of the magnitude of t_{a_1} ,

$$\|\zeta_{c_0}\|_2 \leq e^{-(t_{a_1}/2-1)n^{-O(1)}+O(n^3)} \leq e^{-t_{a_1}n^{-O(1)}} \leq e^{-\tau^2}. \quad (54)$$

where $\tau = \frac{1}{2}t_{a_1}^{1/3}$. The rest of the sequence $\{c_i\}$ is now entirely specified. In particular, note that $c_1 = a_1$ and $d_0 = b_0$. By extension, $\mathbf{m}_{c_0} = \mathbf{m}_a$; so, by (45),

$$\|\mathbf{m}_{c_0} - \mathbf{m}_{b_0}\|_2 \leq \frac{\log t_{a_1}}{t_{a_1}} n^{O(n^3)} < \frac{1}{\tau}.$$

therefore, $\mathbf{m}_{c_0} = \mathbf{m}_{b_0} + \mu_{c_0}$, where

$$\|\mu_{c_0}\|_2 < \frac{1}{\tau}. \quad (55)$$

As we shall see, the presence of the square τ^2 in the exponent of (54) ensures that the oscillations of F_{c_0} are too small to interfere with the residue $\|\mu_{c_0}\|_2$. Writing $\tilde{\mathbf{m}}_{c_0} = \mathbf{m}_{b_0}$, it follows from (53) that

$$v_{c_0}(t_{c_0}) = (\mathbf{1}_{n_{c_0}} \otimes I_d) \tilde{\mathbf{m}}_{c_0} + (\mathbf{1}_{n_{c_0}} \otimes I_d) \mu_{c_0} + \zeta_{c_0},$$

which matches (51), with $u_{c_0} = \mathbf{1}_{n_{c_0}}$. Since all the nodes d_i are of the form b_{j_i} ,

$$t_{d_i} < \sqrt{\log \log t_{a_0}} < \log \log \tau.$$

Thus, we will be able to apply Lemma 3.32 once we verify that all conditions in (52) are met:

- [$2^{t_f} \leq \tau \leq t_{c_0}^{1/3}$]: This follows from our setting $\tau = \frac{1}{2}(t_{c_0} + 1)^{1/3}$ and our assumption that $t_{a_1} > 2^{2^{t_f}}$.
- [$\ell(\tilde{\mathbf{m}}_{c_0}) = O(\log \log \tau)$]: Because $\tau > 2^{2^{t_f-2}}$,

$$\sqrt{\log \log t_{a_0}} n \log n < (\log \log t_{a_0})^{2/3} = o(\log \log \tau).$$

The desired bound follows from (44):

$$\ell(\tilde{\mathbf{m}}_{c_0}) = \ell(\mathbf{m}_{b_0}) = O(t_{b_0} n \log n) = O(\sqrt{\log \log t_{a_0}} n \log n) < \log \log \tau.$$

- [$e^{-\tau n^{O(1)}} \leq \|\mu_{c_0}\|_2 \leq \frac{1}{\tau}$]: The upper bound comes from (55). For the lower bound, note that $\mathbf{m}_{c_0} = \mathbf{m}_a$, with $t_a \leq t_{a_0} 2^{n^{O(1)}}$. Another application of (44) shows that

$$\ell(\mathbf{m}_{c_0}) = O(t_a n \log n) < t_{a_0}^{7/6} < \tau.$$

We just saw that $\ell(\mathbf{m}_{b_0}) < \log \log \tau$, so $\mu_{c_0} = \mathbf{m}_{c_0} - \mathbf{m}_{b_0}$ is a d -dimensional vector with rational coordinates over fewer than 2τ bits. The lower bound follows from the fact that $\mu_{c_0} \neq 0$. By Lemma 3.22, the stationary velocities \mathbf{m}_{c_0} and \mathbf{m}_{b_0} cannot be equal, otherwise the two flocks F_a and F_{b_0} could not take so long to meet at time t_{a_1} . Indeed, the time elapsed would be at least $t_{a_1} - t_a$, (since $t_a > t_{b_0}$), which would greatly exceed the limit of $t_a 2^{n^{O(1)}}$ allowed.

- [$\|u_{c_0}\|_\infty = 1$ & $u_{c_0} \geq 0$ & $\|\zeta_{c_0}\|_2 \leq e^{-\tau^2 n^{-O(1)} + n^{O(1)}}$]: The bounds follow from (54) and $u_{c_0} = \mathbf{1}_{n_{a_0}}$.

Let c_l be the node a_k . By applying Lemma 3.32 at c_l , we find that $\mathbf{m}_{b_{k-1}} = \tilde{\mathbf{m}}_{c_{l-1}}$. Applying the same lemma now at node c_{l-1} shows that

$$v_{c_{l-1}}(t_{c_{l-1}}) = (\mathbf{1}_{n_{c_{l-1}}} \otimes I_d) \tilde{\mathbf{m}}_{c_{l-1}} + (u_{c_{l-1}} \otimes I_d) \mu_{c_{l-1}} + \zeta_{c_{l-1}},$$

where

$$\begin{cases} \|\mu_{c_{l-1}}\|_2 \geq e^{-\tau n^{O(1)}} \\ \|u_{c_{l-1}}\|_\infty = 1 \ \& \ u_{c_{l-1}} \geq 0; \\ \|\zeta_{c_{l-1}}\|_2 \leq e^{-\tau^2 n^{-O(1)} + n^{O(1)}}. \end{cases}$$

The lemma also allows us to express the stationary velocity at c_{l-1} :

$$\begin{aligned} \mathbf{m}_{c_{l-1}} &= (\pi_{c_{l-1}}^T \otimes I_d) v_{c_{l-1}}(t_{c_{l-1}}) \\ &= (\pi_{c_{l-1}}^T \otimes I_d) ((\mathbf{1}_{n_{c_{l-1}}} \otimes I_d) \tilde{\mathbf{m}}_{c_{l-1}} + (u_{c_{l-1}} \otimes I_d) \mu_{c_{l-1}} + \zeta_{c_{l-1}}) \\ &= \mathbf{m}_{b_{k-1}} + (\pi_{c_{l-1}}^T u_{c_{l-1}} \otimes I_d) \mu_{c_{l-1}} + (\pi_{c_{l-1}}^T \otimes I_d) \zeta_{c_{l-1}}. \end{aligned}$$

By the triangle inequality, it follows that

$$\begin{aligned} \|\mathbf{m}_{c_{l-1}} - \mathbf{m}_{b_{k-1}}\|_2 &\geq \|(\pi_{c_{l-1}}^T u_{c_{l-1}} \otimes I_d) \mu_{c_{l-1}}\|_2 - \|(\pi_{c_{l-1}}^T \otimes I_d) \zeta_{c_{l-1}}\|_2 \\ &\geq \pi_{c_{l-1}}^T u_{c_{l-1}} \|\mu_{c_{l-1}}\|_2 - \|(\pi_{c_{l-1}}^T \otimes I_d)\|_F \|\zeta_{c_{l-1}}\|_2 \\ &\geq \min_i \{(\pi_{c_{l-1}})_i\} e^{-\tau n^{O(1)}} - \sqrt{d} e^{-\tau^2 n^{-O(1)} + n^{O(1)}} \geq e^{-\tau n^{O(1)}}. \end{aligned}$$

By (45),

$$\|\mathbf{m}_{c_{l-1}} - \mathbf{m}_{b_{k-1}}\|_2 \leq \frac{\log t_{a_k}}{t_{a_k}} n^{O(n^3)};$$

therefore, since $t_{a_k} > 2^{t_f} > n^{n^4}$,

$$t_{a_k} \leq \|\mathbf{m}_{c_{l-1}} - \mathbf{m}_{b_{k-1}}\|_2^{-2} \leq e^{\tau n^{O(1)}} \leq e^{\tau^{1.5}},$$

which contradicts our assumption that $\tau = \frac{1}{2} t_{a_1}^{1/3} < (\log t_{a_k})^{1/3}$. \square

Proof of Lemma 3.31. Using the shorthand $u^a = P_a^{t_c - t_a} u_a$ and $\zeta^a = (P_a^{t_c - t_a} \otimes I_d) \zeta_a$, we express the velocity of the flock F_a at time t_c . From

$$v_a(t_c) = (P_a^{t_c - t_a} \otimes I_d) v_a(t_a),$$

we find that, by (51),

$$\begin{aligned} v_a(t_c) &= (P_a^{t_c - t_a} \otimes I_d) (\mathbf{1}_{n_a} \otimes I_d) \tilde{\mathbf{m}}_a + (P_a^{t_c - t_a} \otimes I_d) (u_a \otimes I_d) \mu_a + \zeta^a \\ &= (\mathbf{1}_{n_a} \otimes I_d) \tilde{\mathbf{m}}_a + (u^a \otimes I_d) \mu_a + \zeta^a. \end{aligned} \tag{56}$$

Because P_a is an averaging operator, $\|P_a^{t_c - t_a} u_a\|_\infty \leq \|u_a\|_\infty = 1$. The vector u_a is nonnegative, so

$$\begin{aligned} \|P_a^{t_c - t_a} u_a\|_\infty &\geq \frac{1}{n_a} \|P_a^{t_c - t_a} u_a\|_1 = \frac{1}{n_a} \mathbf{1}_{n_a}^T P_a^{t_c - t_a} u_a \geq \frac{1}{n_a} \pi_a^T P_a^{t_c - t_a} u_a \\ &\geq \frac{1}{n_a} \pi_a^T u_a \geq \frac{1}{n_a} \min_i \{(\pi_a)_i\} \|u_a\|_\infty \geq n^{-O(1)}. \end{aligned}$$

Similarly, by convexity,

$$\begin{aligned} \|(P_a^{t_c-t_a} \otimes I_d)\zeta_a\|_2 &\leq \sqrt{dn_a} \|(P_a^{t_c-t_a} \otimes I_d)\zeta_a\|_\infty \\ &\leq \sqrt{dn_a} \|\zeta_a\|_\infty \leq \sqrt{dn_a} \|\zeta_a\|_2; \end{aligned}$$

therefore,

$$\begin{cases} n^{-O(1)} \leq \|u^a\|_\infty \leq 1 \ \& \ u^a \geq 0; \\ \|\zeta^a\|_2 \leq n\|\zeta_a\|_2. \end{cases} \quad (57)$$

Case I. Node b is well defined and $t_b < \log \log \tau$: Since, by (52), $t_c > t_a \geq \tau^3 \geq 8^{t_f}$, with $t_f = n^{f_0 n^3}$,

$$-(t_c - t_b)n^{-O(1)} + \Theta(n^3) \leq -\tau^2;$$

so, by applying (43) to the flock F_b , we find that

$$\|v_b(t_c) - (\mathbf{1}_{n_b} \otimes I_d)\mathbf{m}_b\|_2 \leq e^{-(t_c-t_b)n^{-O(1)}+O(n^3)};$$

hence

$$v_b(t_c) = (\mathbf{1}_{n_b} \otimes I_d)\mathbf{m}_b + e^{-\tau^2} z_c,$$

where $\|z_c\|_2 \leq 1$. It follows from (56) that

$$\begin{aligned} v_c(t_c) &= \begin{pmatrix} v_a(t_c) \\ v_b(t_c) \end{pmatrix} = \begin{pmatrix} (\mathbf{1}_{n_a} \otimes I_d)\tilde{\mathbf{m}}_a \\ (\mathbf{1}_{n_b} \otimes I_d)\mathbf{m}_b \end{pmatrix} + \begin{pmatrix} (u^a \otimes I_d)\mu_a \\ 0 \end{pmatrix} + \begin{pmatrix} \zeta^a \\ e^{-\tau^2} z_c \end{pmatrix} \\ &= \begin{pmatrix} (\mathbf{1}_{n_a} \otimes I_d)\tilde{\mathbf{m}}_a \\ (\mathbf{1}_{n_b} \otimes I_d)\mathbf{m}_b \end{pmatrix} + \left\{ \begin{pmatrix} u^a \\ 0 \end{pmatrix} \otimes I_d \right\} \mu_a + \begin{pmatrix} \zeta^a \\ e^{-\tau^2} z_c \end{pmatrix}. \end{aligned} \quad (58)$$

By (51), the stationary velocity of F_a is equal to

$$\begin{aligned} \mathbf{m}_a &= (\pi_a^T \otimes I_d)v_a(t_a) = (\pi_a^T \otimes I_d)((\mathbf{1}_{n_a} \otimes I_d)\tilde{\mathbf{m}}_a + (u_a \otimes I_d)\mu_a + \zeta_a) \\ &= \tilde{\mathbf{m}}_a + (\pi_a^T u_a)\mu_a + (\pi_a^T \otimes I_d)\zeta_a. \end{aligned} \quad (59)$$

By the triangle inequality, it follows that

$$\begin{aligned} \|\mathbf{m}_a - \tilde{\mathbf{m}}_a\|_2 &\geq \pi_a^T u_a \|\mu_a\|_2 - \|(\pi_a^T \otimes I_d)\|_F \|\zeta_a\|_2 \\ &\geq \min_i \{(\pi_a)_i\} e^{-\tau n^{O(1)}} - \sqrt{d} e^{-\tau^2 n^{-O(1)} + n^{O(1)}} \geq e^{-\tau n^{O(1)}}; \end{aligned}$$

which shows that

$$\mathbf{m}_a \neq \tilde{\mathbf{m}}_a. \quad (60)$$

Note also that, by (59),

$$\begin{aligned} \|\tilde{\mathbf{m}}_a - \mathbf{m}_b\|_2 &\leq \|\tilde{\mathbf{m}}_a - \mathbf{m}_a\|_2 + \|\mathbf{m}_a - \mathbf{m}_b\|_2 \\ &\leq \pi_a^T u_a \|\mu_a\|_2 + \|\pi_a^T \otimes I_d\|_F \|\zeta_a\|_2 + \|\mathbf{m}_a - \mathbf{m}_b\|_2. \end{aligned}$$

We bound each term on the right-hand side: by (52) and Cauchy-Schwarz,

$$\pi_a^T u_a \|\mu_a\|_2 \leq \frac{1}{\tau} \|\pi_a\|_2 \|u_a\|_2 \leq \frac{1}{\tau} \sqrt{n_a} \|u_a\|_\infty \leq \frac{1}{\tau} \sqrt{n}.$$

By (45) and $t_c > \tau^3 \geq 8^{t_f}$,

$$\|\mathbf{m}_a - \mathbf{m}_b\|_2 \leq \frac{1}{\tau}.$$

Also, $\|\pi_a^T \otimes I_d\|_F = O(1)$ and, by (52), $\|\zeta_a\|_2 \leq e^{-\tau^2 n^{-O(1)} + n^{O(1)}}$; therefore

$$\|\tilde{\mathbf{m}}_a - \mathbf{m}_b\|_2 < \sqrt{\frac{1}{\tau}}.$$

By (44), our assumption that $t_b < \log \log \tau$ implies that

$$\ell(\mathbf{m}_b) = O(n(\log n) \log \log \tau) < (\log \log \tau)^2.$$

Since, by (52), $\ell(\tilde{\mathbf{m}}_a) = O(\log \log \tau)$, the squared distance $\|\tilde{\mathbf{m}}_a - \mathbf{m}_b\|_2^2$ is a rational over $O(\log \log \tau)^2$ bits: being less than $1/\tau$ implies that it is actually zero; hence $\tilde{\mathbf{m}}_a = \mathbf{m}_b$, as claimed in the lemma. We verify from (57) that

$$\mu_c \stackrel{\text{def}}{=} \mu_a \|u^a\|_\infty \quad \text{and} \quad u_c \stackrel{\text{def}}{=} \begin{pmatrix} u^a \\ 0 \end{pmatrix} \|u^a\|_\infty^{-1}$$

satisfy the conditions of the lemma. By (58),

$$v_c(t_c) = (\mathbf{1}_{n_c} \otimes I_d) \tilde{\mathbf{m}}_a + (u_c \otimes I_d) \mu_c + \zeta_c,$$

where

$$\zeta_c = \begin{pmatrix} \zeta^a \\ e^{-\tau^2} z_c \end{pmatrix}.$$

By (57) and $\|z_c\|_2 \leq 1$, the lemma's condition on ζ_c is trivially satisfied.

Case II. Node b is not defined: We set $\zeta_c = \zeta^a$; $\mu_c = \mu_a \|u^a\|_\infty$; and $u_c = u^a \|u^a\|_\infty^{-1}$. This matches the identity (56) with the one claimed in the lemma. \square

Proof of Lemma 3.29. Suppose that Bob does not always follow the single-iterated log rule. We show how to force him to do so without decreasing the score differential. If Bob uses the rule $t_B \leftarrow \log \log t_B$, then Alice follows up with $t_A \leftarrow (\log \log t_A)^\alpha$. Let us break this round into two parts:

1. $t_B \leftarrow \log t_B$ and $t_A \leftarrow \log t_A$;
2. $t_B \leftarrow \log t_B$ and $t_A \leftarrow (\log t_A)^\alpha$.

We proceed similarly for higher log-iterations and apply the modification systematically. This transformation increases the scores of the players but it does not change their difference. Finally, we apply one last transformation to the new game, which is to convert all of Alice's moves into $t_A \leftarrow (\log t_A)^{1/4}$. This can only increase the score differential. \square

Proof of Lemma 3.30. Consider the two recurrence relations:

$$a_0(x) = b_0(x) = x,$$

and, for $h > 0$,

$$\begin{cases} a_h(x) = 2^{a_{h-1}(x)} \\ b_h(x) = 2^{b_{h-1}(x)} + 2. \end{cases}$$

Recall that c_h is defined by $c_0 = t_0^4$ and, for $h > 0$, $c_h = 2^{4c_{h-1}}$. We verify by induction that, for any $h > 0$,

$$c_h = 2^{2^{b_{h-1}(4 \log t_0 + 2)}}.$$

To prove the inequality we seek,

$$\min\{h \mid c_h \geq t\} \geq \log^* t - \log^* t_0 - O(1),$$

where $t > t_0$, we may assume that $t > 2^{t_0}$, otherwise the result is trivial. The assumption implies that the minimum h is positive; therefore it suffices to prove that, for all $h \geq 0$,

$$b_h(4 \log t_0 + 2) \leq a_h(4 \log t_0 + 4). \quad (61)$$

We see by induction that, for all $h \geq 0$, $x \geq 2$, and $\varepsilon > 0$,

$$a_h(x) + \varepsilon \leq a_h(x + \varepsilon 2^{-h}). \quad (62)$$

The case $h = 0$ is obvious, so consider $h > 0$. Note that, for any $y \geq 2$,

$$2^y + \varepsilon \leq 2^{y+\varepsilon/2},$$

which follows from

$$\ln(1 + \varepsilon 2^{-y}) \leq \varepsilon 2^{-y} \leq \frac{\ln 2}{2} \varepsilon.$$

Since $a_{h-1}(x) \geq 2$, this shows that

$$a_h(x) + \varepsilon = 2^{a_{h-1}(x)} + \varepsilon \leq 2^{a_{h-1}(x) + \varepsilon/2} \leq 2^{a_{h-1}(x + \varepsilon 2^{-h})} = a_h(x + \varepsilon 2^{-h}),$$

which proves (62). Next, we show by induction that, for all $h \geq 0$ and $x \geq 2$,

$$b_h(x) \leq a_h(x + 2 - 2^{1-h}). \quad (63)$$

The case $h = 0$ again being obvious, assume that $h > 0$. By (62),

$$\begin{aligned} b_h(x) &= 2^{b_{h-1}(x)} + 2 \leq 2^{a_{h-1}(x + 2 - 2^{2-h})} + 2 \\ &\leq a_h(x + 2 - 2^{2-h}) + 2 \leq a_h(x + 2 - 2^{1-h}), \end{aligned}$$

which establishes (63); and hence (61). \square

4 The Lower Bound

We specify initial positions and velocities for n birds, using only $O(\log n)$ -bits per bird, and prove that their flock network converges only after a number of steps equal to a tower-of-twos of height $\log n$. Our proof is entirely constructive. The hysteresis assumption of the model is not used and, in fact, the lower bound holds whether the model includes hysteresis or not. Our construction is in two dimensions, $d = 2$, but it works for any $d > 0$. The n birds all start from the X -axis (think of them on a wire), and fly in the (X, Y) -plane, merging in twos, fourths, eights, etc, until they form a single connected flock. This process forms a *fusion tree* \mathcal{T} of height $\log n$. (We assume throughout this section that n is a large odd power of two.) Every flock formed in the process is a single path. The transition matrix is that of a lazy symmetric random walk with, at each node, a probability $\frac{1}{3}$ of staying put.

Figure 20: Birds join in flocks of size 2, 4, 8, etc, up in the fusion tree, each time flying in a direction closer to the Y -axis. The angle decreases exponentially at each level, so the time between merges grows accordingly. The big arrow indicates the Markov chain corresponding to a 4-bird flock. At each state, the probability of staying put is $\frac{1}{3}$, with the remaining $\frac{2}{3}$ being distributed uniformly among the outgoing edges.

Initially, the velocity of each bird has its Y -coordinate equal to 1. Since averaging these velocities will only produce 1, the birds move up away from the X -axis forever at constant speed 1. We can then factor out the Y coordinates and focus our entire investigation on the birds' projections on the X -axis. In fact, we might as well view the birds as points moving along the X -axis and joining into edges when their distance is 1 or less. In other words, we let $x(t)$ denote the vector $(x_1(t), \dots, x_n(t))$ and let $v(t) = x(t) - x(t-1)$. The coordinates of the velocity

vector $v(t)$ will quickly decrease, but we should not be mistaken into thinking that the birds slow down accordingly. Because of the Y motion, all the birds will always fly at speeds very near 1. Let c be a large enough odd integer: one will easily check that $c = 11$ works, but no effort was made to find the smallest possible value. We leave c as a symbol to make it easier to follow the derivations.

$$\text{INITIAL CONDITIONS} \left\{ \begin{array}{l} x(0) = \left(0, \frac{2}{3}, 2, \frac{8}{3}, \dots, 2l, 2l + \frac{2}{3}, \dots, n-2, n - \frac{4}{3} \right)^T; \\ v(1) = \left(\underbrace{n^{-c}, 0, -n^{-c}, 0, n^{-c}, 0, \dots, n^{-c}, 0, -n^{-c}, 0}_{n} \right)^T. \end{array} \right.$$

Each nonleaf node a of the fusion tree \mathcal{T} has associated with it a flock of 2^j birds whose network is a single path: the index $j > 0$ is also the height of the node. The flock F_a at node a is formed at a time t_j that depends only on the height in \mathcal{T} ; by convention, $t_1 = 0$. Given a node a at height $j > 0$, we denote by v^a the 2^j -dimensional velocity vector of the flock F_a at time t_j and by \mathbf{m}_a its stationary velocity. For $j > 2$, if l and r denote the left and right children of a , respectively, then $v^l = v^r$. In other words, two sibling flocks start out with the same initial velocity. At time t_j , because of noise called *flipping*, the velocity vectors of these flocks will have evolved into $\mathcal{L}v^l$ and $-\mathcal{L}v^r$, respectively, where \mathcal{L} is a linear transformation specific to that sibling pair. This implies that

$$v^a = \begin{pmatrix} \mathcal{L}v^l \\ -\mathcal{L}v^r \end{pmatrix}.$$

The stationary velocity of the flock F_a satisfies

$$\mathbf{m}_a = \frac{1}{2^{j-1}} \left(\overbrace{\frac{1}{2}, 1, \dots, 1, \frac{1}{2}}^{2^j} \right) v^a. \quad (64)$$

The initial conditions provide the velocity vectors of the 2-bird flocks at height 1 one step after $t = 0$. It follows that, if a is a node at height $j = 1$, the stationary velocity \mathbf{m}_a is equal to $\frac{1}{2}(-1)^{k+1}n^{-c}$, where k is the rank of v among the nodes at height 1 from left to right. For consistency, we must set $v^a = (-1)^k n^{-c} (1, -2)^T$. This choice is dictated by the initial conditions set above, so that, for any $j \geq 1$, the velocity of the flock at v at time t ($t_j \leq t < t_{j+1}$) is equal to $P_j^{t-t_j} v^a$, where

$$P_j = \frac{1}{3} \underbrace{\begin{pmatrix} 1 & 2 & 0 & 0 & \dots & 0 \\ 1 & 1 & 1 & 0 & \dots & 0 \\ 0 & 1 & 1 & 1 & \dots & 0 \\ \vdots & \ddots & & & \ddots & \vdots \\ 0 & \dots & 0 & 1 & 1 & 1 \\ 0 & \dots & 0 & 0 & 2 & 1 \end{pmatrix}}_{2^j}. \quad (65)$$

At height 2 and above, some flocks undergo a *velocity flip* at chosen times: this means that the sign of their current velocity is reversed and it becomes $-P_j^{t-t_j} v^a$ at time t . By abuse of notation, we say that the node flips: it is instantaneous and does not count as an averaging transition. When does this happen and why? Fix an integer $f = 3$. Again, we leave this constant as a symbol for clarity.

FLIPPING RULE: It applies at time $t = t_j + n^f$ to any flock of a left child of even height $j > 1$ and to any flock of a right child of odd height $j > 2$.

Figure 21: Flipping alternates between left and right. Leaves were added to indicate that nodes at height 1 correspond to 2-bird flocks.

Flips are convenient to make flocks collide. We show later that they conform to the noisy flocking model. At height 2 and higher, any two sibling nodes l and r are assigned the same velocity vector $v^l = v^r$. Their corresponding flocks evolve in parallel for n^f steps, like two identical copies. Then, one of them “flips” (which one, left or right, depends on the height in the tree), meaning that the two velocity vectors become opposite of each other. The flip type alternates between left and right as we go up the tree. Although flipping has only a trivial effect on velocities, which decays over time, we must be careful that it does not break flocks apart. We could rely on hysteresis to prevent this from happening, but as we said earlier we seek a lower bound that holds whether hysteresis is present or not. That is why we introduce the lag n^f . The averaging operations act like glue and the glue needs to dry up before changing direction.

Up to sign, v^a depends only on the height j of node a , so we focus our attention on the left spine of the tree, denoted $a_1, \dots, a_{\log n}$ in ascending order. The exact

behavior of every flock in the system can be found in replica either at a node a_j or at a sibling of such a node. That is why, when checking the structural integrity of the flocks, it is not quite enough to concentrate on the left spine: we must also check the right children hanging off of it. For any $1 \leq j < \log n$, we define $\theta_j = t_{j+1} - t_j$ as shorthand for the lifetime of the flock F_{a_j} . Our task is two-fold. First, we must show that $|\mathbf{m}_{a_j}|$ decreases very fast: we prove that (roughly)

$$|\mathbf{m}_{a_j}| < e^{-\Omega(|\mathbf{m}_{a_{j-1}}^{-1}|)},$$

which implies that θ_j is exponentially larger than θ_{j-1} ; hence the logarithmic tower-of-twos lower bound. Second, we must prove the integrity of the scheme: that each flock remains a single path over its lifetime; that two flocks meet when and where they should; that flipping fits within the model; etc.

4.1 The Early Phases

The proofs are technical but one can develop some intuition for the process they mean to explain by working out the calculations for \mathbf{m}_{a_j} ($j = 1, 2, 3$) explicitly. At time $t = t_1 = 0$, the network consists of the edges $(1, 2), (3, 4), \dots, (n-1, n)$. We already saw that the 2-bird flock $(\mathcal{B}_1, \mathcal{B}_2)$ has initial and stationary velocities

$$v^{a_1} = n^{-c} \begin{pmatrix} -1 \\ 2 \end{pmatrix} \quad \text{and} \quad \mathbf{m}_{a_1} = \frac{1}{2}n^{-c}. \quad (66)$$

Flying at Height 1. Because the velocity at time t captures the motion *ending* at t , the velocity of the flock $(\mathcal{B}_1, \mathcal{B}_2)$ at time 1 is $P_1 v^{a_1}$. By (15), for $t > 0$,

$$x(t) = x(0) + \sum_{s=0}^{t-1} P^s v(1),$$

which gives us

$$\begin{pmatrix} x_1(t) \\ x_2(t) \end{pmatrix} = \begin{pmatrix} x_1(0) \\ x_2(0) \end{pmatrix} + \sum_{s=0}^{t-1} P_1^s (P_1 v^{a_1}) = \frac{2}{3} \begin{pmatrix} 0 \\ 1 \end{pmatrix} + \sum_{s=0}^{t-1} P_1^s \begin{pmatrix} n^{-c} \\ 0 \end{pmatrix}.$$

Diagonalizing P_1 shows that, for any integer $s > 0$,

$$P_1^s = \frac{1}{2} \begin{pmatrix} 1 \\ 1 \end{pmatrix} (1 \quad 1) + \frac{1}{2} (-3)^{-s} \begin{pmatrix} 1 \\ -1 \end{pmatrix} (1 \quad -1).$$

It follows that, for $0 = t_1 < t \leq t_2$,

$$\begin{cases} x_1(t) = \frac{t}{2}n^{-c} + \frac{1}{2}n^{-c} \sum_{s=0}^{t-1} (-3)^{-s} = \frac{1}{2}n^{-c} (t + \frac{3}{4} + \frac{1}{4}(-3)^{1-t}); \\ x_2(t) = \frac{2}{3} + \frac{t}{2}n^{-c} - \frac{1}{2}n^{-c} \sum_{s=0}^{t-1} (-3)^{-s} = \frac{2}{3} + \frac{1}{2}n^{-c} (t - \frac{3}{4} - \frac{1}{4}(-3)^{1-t}). \end{cases} \quad (67)$$

Note that \mathcal{B}_1 always stays to the left of \mathcal{B}_2 and their distance is

$$x_2(t) - x_1(t) = \frac{2}{3} - \frac{3}{4}n^{-c} (1 - (-\frac{1}{3})^t). \quad (68)$$

Left to their own devices, the two birds would slide to the right at speed \mathbf{m}_{a_1} , plus or minus an exponentially vanishing term; their distance would oscillate around $\frac{2}{3} - \frac{3}{4}n^{-c}$ and converge exponentially fast, with the oscillation created by the negative eigenvalue. This is what happens until the flock at a_1 begins to interact with its “sibling” flock to the right, $(\mathcal{B}_3, \mathcal{B}_4)$. The latter’s velocity vector is $(-n^{-c}, 0)^T$ at time $t = 1$ and, for $t_1 < t \leq t_2$,

$$\begin{cases} x_3(t) = 2 - \frac{1}{2}n^{-c} (t + \frac{3}{4} + \frac{1}{4}(-3)^{1-t}); \\ x_4(t) = \frac{8}{3} - \frac{1}{2}n^{-c} (t - \frac{3}{4} - \frac{1}{4}(-3)^{1-t}). \end{cases} \quad (69)$$

The stationary velocity of $(\mathcal{B}_3, \mathcal{B}_4)$ is $-\mathbf{m}_{a_1} = -\frac{1}{2}n^{-c}$, but the flock is *not* the mirror image of $(\mathcal{B}_1, \mathcal{B}_2)$, a situation that would bring the flocking to an end. In particular, note that the diameter of the flock is

$$x_4(t) - x_3(t) = \frac{2}{3} + \frac{3}{4}n^{-c} (1 - (-\frac{1}{3})^t), \quad (70)$$

which always exceeds that of $(\mathcal{B}_1, \mathcal{B}_2)$ for all $t > 0$. The diameters of both flocks oscillate around $\frac{2}{3}$ but in phase opposition: indeed, their sum remains constant. Both 2-bird flocks drift toward each other at distance¹² $x_3(t) - x_2(t) = \frac{4}{3} - tn^{-c}$. This implies that $t_2 = t_1 + \theta_1 = \lceil \frac{1}{3}n^c \rceil$. Because n is an odd power of two and c is odd, $n^c = 2 \pmod{6}$; hence, $\lceil \frac{1}{3}n^c \rceil = \frac{1}{3}(n^c + 1)$ and

$$t_2 = \theta_1 = \frac{1}{3}(n^c + 1) = 1 \pmod{2} \quad (71)$$

We conclude that

$$x_3(t_2) - x_2(t_2) = 1 - \frac{1}{3}n^{-c}. \quad (72)$$

The definition of flip nodes suggests a cyclic process with period 2 that is inherent to the flocking process. At time t_2 , the flock at a_2 is formed with the initial velocity

$$v^{a_2} = \begin{pmatrix} P_1^{t_2-t_1} v^{a_1} \\ -P_1^{t_2-t_1} v^{a_1} \end{pmatrix} = \begin{pmatrix} P_1^{\theta_1-1} \begin{pmatrix} n^{-c} \\ 0 \end{pmatrix} \\ -P_1^{\theta_1-1} \begin{pmatrix} n^{-c} \\ 0 \end{pmatrix} \end{pmatrix} = \frac{1}{2}n^{-c} \begin{pmatrix} 1 + (-3)^{1-\theta_1} \\ 1 - (-3)^{1-\theta_1} \\ -1 - (-3)^{1-\theta_1} \\ -1 + (-3)^{1-\theta_1} \end{pmatrix}. \quad (73)$$

By (64), the stationary velocity for the 4-bird flock is $\frac{1}{3}(\frac{1}{2}, 1, 1, \frac{1}{2})v^{a_2}$; hence, by (66, 71),

$$\begin{aligned} 0 > \mathbf{m}_{a_2} &= \frac{1}{3}(\frac{1}{2}, 1, 1, \frac{1}{2})v^{a_2} = \frac{1}{2}n^{-c}(-3)^{-\theta_1} \\ &= -\frac{1}{2}n^{-c}(\frac{1}{3})^{(n^c+1)/3} \geq -e^{-\Omega(\mathbf{m}_{a_1}^{-1})}. \end{aligned} \quad (74)$$

This inequality gives an inkling of the kind of exponential decay we envision as we go up the fusion tree. Note that $\mathbf{m}_{a_2} < 0$, which means that the flock is drifting in the wrong direction: that is why a_2 is a flip node.

¹²The linearity in t is due to an accidental cancellation that will not occur for bigger flocks.

Figure 22: The 4-bird flock is formed at time t_2 and acquires a negative stationary velocity \mathbf{m}_{a_2} .

Flying at Height 2. Again, by (15), for $t_2 < t \leq t_2 + n^f < t_3$,

$$\begin{pmatrix} x_1(t) \\ \vdots \\ x_4(t) \end{pmatrix} = \begin{pmatrix} x_1(t_2) \\ \vdots \\ x_4(t_2) \end{pmatrix} + \sum_{s=0}^{t-t_2-1} P_2^{s+1} v^{a_2}, \quad \text{with } P_2 = \frac{1}{3} \begin{pmatrix} 1 & 2 & 0 & 0 \\ 1 & 1 & 1 & 0 \\ 0 & 1 & 1 & 1 \\ 0 & 0 & 2 & 1 \end{pmatrix}.$$

By straightforward diagonalization, we find that, for any integer $s > 0$,

$$P_2^s = \frac{1}{6} \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} (1, 2, 2, 1) + \frac{1}{6} \left(\frac{2}{3}\right)^s \begin{pmatrix} 2 \\ 1 \\ -1 \\ -2 \end{pmatrix} (1, 1, -1, -1) + \frac{1}{6} (-3)^{-s} \begin{pmatrix} 1 \\ -1 \\ 1 \\ -1 \end{pmatrix} (1, -2, 2, -1); \quad (75)$$

therefore,

$$\begin{aligned} \begin{pmatrix} x_1(t) \\ \vdots \\ x_4(t) \end{pmatrix} &= \begin{pmatrix} x_1(t_2) \\ \vdots \\ x_4(t_2) \end{pmatrix} + \mathbf{m}_{a_2}(t - t_2) \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} + \frac{1}{8}n^{-c} \begin{pmatrix} 11 \\ 5 \\ -5 \\ -11 \end{pmatrix} \\ &\quad + n^{-c} \left(\frac{2}{3}\right)^{t-t_2+1} \begin{pmatrix} -2 \\ -1 \\ 1 \\ 2 \end{pmatrix} + \frac{1}{24}n^{-c}(-3)^{t_2-t} \begin{pmatrix} -1 \\ 1 \\ -1 \\ 1 \end{pmatrix}. \end{aligned} \quad (76)$$

It follows from (68, 70) that, for $t_2 < t \leq t_2 + n^f$, both $x_2(t) - x_1(t)$ and $x_4(t) - x_3(t)$ are $\frac{2}{3} \pm O(n^{-c})$; therefore, the two end edges of the 4-bird flock are *safe*, which we define as being of length less than 1 (so as to belong to the flocking network) but greater than $\frac{1}{2}$ (so as to avoid edges joining nonconsecutive birds). The middle one, (2, 3), is more problematic. Its length is

$$x_3(t) - x_2(t) = x_3(t_2) - x_2(t_2) - \frac{1}{12}n^{-c} (15 - 16(\frac{2}{3})^{t-t_2} + (-3)^{t_2-t}).$$

We can verify that

$$15 - 16(\frac{2}{3})^{t-t_2} + (-3)^{t_2-t} \geq 0,$$

for all $t > t_2$, which, by (72), shows that the distance between the two middle birds $\mathcal{B}_2, \mathcal{B}_3$ always lies comfortably between $1 - (\frac{1}{3} + O(1))n^{-c}$ and $1 - \frac{1}{3}n^{-c}$. The upper bound is both lucky and intuitive: lucky because the edge starts with length very near 1 and it could easily be perturbed and break up; intuitive because the two flocks have inertia when they bump into each other and one expects the edge (2, 3) to act like a spring being compressed, thereby shrinking during the initial steps.

Flipping Velocity at Height 2. Since a_2 is a flip node, the velocity vector reverses sign after a lag of n^f steps. Instead of redoing all the calculations, we can apply a simple symmetry principle: by linearity, the positions of the flock with and without the flip average out to what it was at time $t_2 + n^f$ (Figure 23). In other words, for $t_2 + n^f < t \leq t_3$,

$$\begin{pmatrix} x_1(t_2 + n^f) \\ \vdots \\ x_4(t_2 + n^f) \end{pmatrix} = \frac{1}{2} \left\{ \begin{pmatrix} x_1(t) \\ \vdots \\ x_4(t) \end{pmatrix}_{flip} + \begin{pmatrix} x_1(t) \\ \vdots \\ x_4(t) \end{pmatrix}_{no-flip} \right\}.$$

Figure 23: The 4-bird flock at a_2 “flips” at time $t_2 + n^f$.

By (76), the position formula for the flock can be readily updated:

$$\begin{aligned}
 \begin{pmatrix} x_1(t) \\ \vdots \\ x_4(t) \end{pmatrix} &= \begin{pmatrix} x_1(t_2) \\ \vdots \\ x_4(t_2) \end{pmatrix} + \mathbf{m}_{a_2}(2n^f + t_2 - t) \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} + \frac{1}{8}n^{-c} \begin{pmatrix} 11 \\ 5 \\ -5 \\ -11 \end{pmatrix} \\
 &\quad + n^{-c} \left(\frac{2}{3}\right)^{n^f+1} \left(2 - \left(\frac{2}{3}\right)^{t-t_2-n^f}\right) \begin{pmatrix} -2 \\ -1 \\ 1 \\ 2 \end{pmatrix} \\
 &\quad + \frac{1}{24}n^{-c}(-3)^{-n^f} \left(2 - (-3)^{t_2+n^f-t}\right) \begin{pmatrix} -1 \\ 1 \\ -1 \\ 1 \end{pmatrix}. \quad (77)
 \end{aligned}$$

This proves that the lengths of the two end edges differ by what they were at t_2 by only $O(n^{-c})$. Indeed, by (68, 70), this implies that, for any $t \leq t_3$,

$$\begin{cases} x_2(t) - x_1(t) = \frac{2}{3} \pm O(n^{-c}); \\ x_4(t) - x_3(t) = \frac{2}{3} \pm O(n^{-c}). \end{cases} \quad (78)$$

The middle edge has length

$$x_3(t) - x_2(t) = x_3(t_2) - x_2(t_2) - \frac{5}{4}n^{-c} + 2n^{-c} \left(\frac{2}{3}\right)^{n^f+1} \left(2 - \left(\frac{2}{3}\right)^{t-t_2-n^f}\right) - \frac{1}{12}n^{-c}(-3)^{-n^f} \left(2 - (-3)^{t_2+n^f-t}\right),$$

which, in view of (72), shows that, for $t_2 + n^f < t \leq t_3$,

$$1 - O(n^{-c}) \leq x_3(t) - x_2(t) \leq 1 - \frac{3}{2}n^{-c}. \quad (79)$$

This proves that the middle edge is safe and the integrity of the entire 4-bird flock is preserved. Was it necessary to delay the flip by n^f ? The particular choice of lag, n^f , will be justified later by examining the bigger flocks, but we can see right away that delaying the flip is mandatory. Indeed, if we replace n^f by 0 in the expression above, then, for $t = t_2 + 2$, we get

$$x_3(t) - x_2(t) = x_3(t_2) - x_2(t_2) + \frac{2}{3}n^{-c} = 1 + \frac{1}{3}n^{-c},$$

which causes the flock to break apart. The flock $(\mathcal{B}_5, \dots, \mathcal{B}_8)$ follows the same trajectory as the 4-bird flock above, shifted along the X -axis by 4 but with no velocity flip. So, by (67, 76), we find that, for $t_2 + n^f < t \leq t_3$,

$$\begin{cases} x_5(t) = x_5(t_2) + \mathbf{m}_{a_2}(t - t_2) + \frac{11}{8}n^{-c} - 2n^{-c}\left(\frac{2}{3}\right)^{t-t_2+1} - \frac{1}{24}n^{-c}(-3)^{t_2-t}; \\ x_5(t_2) = x_1(t_2) + 4 = \frac{1}{2}n^{-c}(t_2 + \frac{3}{4} + \frac{1}{4}(-3)^{1-t_2}) + 4. \end{cases}$$

At the same time, by (77),

$$x_4(t) = x_4(t_2) + \mathbf{m}_{a_2}(2n^f + t_2 - t) - \frac{11}{8}n^{-c} + 2n^{-c} \left(\frac{2}{3}\right)^{n^f+1} \left(2 - \left(\frac{2}{3}\right)^{t-t_2-n^f}\right) + \frac{1}{24}n^{-c}(-3)^{-n^f} \left(2 - (-3)^{t_2+n^f-t}\right),$$

where, by (69),

$$x_4(t_2) = \frac{8}{3} - \frac{1}{2}n^{-c}(t_2 - \frac{3}{4} - \frac{1}{4}(-3)^{1-t_2}).$$

By (71), this shows that, for $t_2 + n^f < t \leq t_3$,

$$\begin{aligned} x_5(t) - x_4(t) &= \frac{4}{3} + t_2n^{-c} + 2\mathbf{m}_{a_2}(t - t_2 - n^f) + \frac{11}{4}n^{-c} \\ &\quad - 4n^{-c} \left(\frac{2}{3}\right)^{n^f+1} - \frac{1}{12}n^{-c}(-3)^{-n^f} \\ &= \frac{5}{3} + \left(\frac{37}{12} \pm o(1)\right)n^{-c} + 2\mathbf{m}_{a_2}(t - t_2 - n^f). \end{aligned}$$

Recall from (74) that \mathbf{m}_{a_2} is negative. This allows the distance $x_5(t) - x_4(t)$ to fall below 1. This happens at $t_3 = t_2 + \theta_2$, where $\theta_2 = n^f + \Theta(|\mathbf{m}_{a_2}^{-1}|)$. Note that $|\mathbf{m}_{a_2}|$ is sufficiently small for the newly formed edge (4, 5) to be safe at time t_3 . We can see that from (74), which also shows that

$$\theta_2 \geq \Omega(|\mathbf{m}_{a_2}^{-1}|) \geq e^{\Omega(\mathbf{m}_{a_1}^{-1})}. \quad (80)$$

We conclude this opening analysis with an estimation of the stationary velocity \mathbf{m}_{a_3} . The flipping rule causes the velocity of the flock $(\mathcal{B}_1, \dots, \mathcal{B}_4)$ to be reversed at time $t_2 + n^f$. (It's a flip of type "left," so named because it involves a left child.) Following the flip, the velocity of the 8-bird flock at a_3 is, at its creation,

$$v^{a_3} = \begin{pmatrix} -P_2^{\theta_2} v^{a_2} \\ P_2^{\theta_2} v^{a_2} \end{pmatrix}.$$

By (73, 75),

$$P_2^{\theta_2} v^{a_2} = \frac{1}{12} n^{-c} \left\{ -2 \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} (-3)^{1-\theta_1} + 4 \left(\frac{2}{3}\right)^{\theta_2} \begin{pmatrix} 2 \\ 1 \\ -1 \\ -2 \end{pmatrix} - 2(-3)^{-\theta_2} \begin{pmatrix} 1 \\ -1 \\ 1 \\ -1 \end{pmatrix} \right\}.$$

By (64, 80), therefore,

$$\begin{aligned} \mathbf{m}_{a_3} &= \frac{1}{7} \left(\frac{1}{2}, 1, 1, 1, 1, 1, 1, \frac{1}{2}\right) \begin{pmatrix} -P_2^{\theta_2} v^{a_2} \\ P_2^{\theta_2} v^{a_2} \end{pmatrix} = \frac{1}{7} \left(\frac{1}{2}, 0, 0, -\frac{1}{2}\right) P_2^{\theta_2} v^{a_2} \\ &= \frac{1}{42} n^{-c} \left(4 \left(\frac{2}{3}\right)^{\theta_2} - (-3)^{-\theta_2} \right) \leq e^{-e^{\Omega(\mathbf{m}_{a_1}^{-1})}}. \end{aligned}$$

Since $\mathbf{m}_{a_3} > 0$, the next flip must be of type "right," which happens to agree with the flipping rule. Observe from (66, 74) how, as j increases from 1 to 3, the stationary velocity \mathbf{m}_{a_j} decays from polynomial to exponential to doubly exponential. To generalize this to further heights is not difficult. What's tricky is to show that, despite all the symmetries in the system, the stationary velocities never vanish. For example, if we formed new flocks by attaching to a smaller one its mirror image, this would bring the drifting motion, and hence the flocking, to an end. We summarize our findings below (66, 71, 74, 80):

$$\begin{cases} |\mathbf{m}_{a_1}| = \frac{1}{2} n^{-c} & \& \theta_1 = \frac{1}{3}(n^c + 1); \\ |\mathbf{m}_{a_2}| \leq e^{-\Omega(\mathbf{m}_{a_1}^{-1})} & \& \theta_2 \geq \Omega(|\mathbf{m}_{a_2}^{-1}|) \geq e^{n^c - 1}; \\ |\mathbf{m}_{a_3}| \leq e^{-e^{n^c - 1}}. \end{cases} \quad (81)$$

4.2 Velocity Analysis

Our first task is to diagonalize the transition matrix P_j given in (65). The Laplacian acting on a path is akin to its acting on a folded cycle. Since the Fourier transform over a finite cyclic group diagonalizes the one-dimensional Laplacian, we can interpret the spectral shift as a linear operator acting on the Fourier coefficients. We explain why below.

The Folded Cycle. The Fourier transform over the additive group \mathbb{Z}_m provides the eigenvectors y_1, \dots, y_m of the linear map \mathcal{M} defined by the circulant matrix

$$\frac{1}{3} \underbrace{\begin{pmatrix} 1 & 1 & 0 & 0 & \dots & 1 \\ 1 & 1 & 1 & 0 & \dots & 0 \\ 0 & 1 & 1 & 1 & \dots & 0 \\ \vdots & \ddots & & & \ddots & \vdots \\ 0 & \dots & 0 & 1 & 1 & 1 \\ 1 & \dots & 0 & 0 & 1 & 1 \end{pmatrix}}_m;$$

namely,

$$y_k = \left(1, e^{2\pi i(k-1)/m}, \dots, e^{2\pi i(k-1)(m-1)/m} \right).$$

The associated eigenvalue λ_k is equal to

$$\frac{1}{3} \left(1 + 2 \cos \frac{2\pi(k-1)}{m} \right).$$

We shall see shortly why using the notation λ_k , reserved for the eigenvalue of P_j , is legitimate. To see the relation with P_j , set $m = 2n - 2$ and $n = 2^j$, and note that the eigenvector coordinates $(y_k)_j$ and $(y_k)_{m+2-j}$ are conjugates. This implies that $\Re y_k$ is a real eigenvector of \mathcal{M} that lies in the n -dimensional linear subspace

$$\mathcal{F} = \bigcap_{j=2}^m \left\{ x_j - x_{m+2-j} = 0 \right\}.$$

Furthermore, it is immediate that P_j is equivalent to the restriction of \mathcal{M} to \mathcal{F} ; in other words, folding the cycle in the middle by identifying opposite sides creates the desired averaging weights (in particular, $2/3$ at the end nodes) and transform the Fourier vectors into right eigenvectors for P_j (hence the valid choice of the notation λ_k). It follows that, for $1 < k \leq 2^j$,

$$u_k = \left(1, \cos \frac{\pi(k-1)}{n-1}, \dots, \cos \frac{\pi(k-1)(n-2)}{n-1}, (-1)^{k-1} \right)^T$$

is the unique right eigenvector (up to scaling) of P_j for λ_k . We note that, unlike for the m -cycle, the transition for the n -path has only simple eigenvalues.

Consider the evolution of a flock at node a_j for $j \geq 1$. Let

$$\pi = \frac{1}{2^j - 1} \overbrace{\left(\frac{1}{2}, 1, \dots, 1, \frac{1}{2} \right)}^{2^j} \quad \text{and} \quad \text{diag } C_j = \frac{1}{3} \overbrace{\left(2, 1, \dots, 1, 2 \right)}^{2^j}. \quad (82)$$

Figure 24: The folded m -cycle. Identifying opposite nodes allows us to use the harmonic analysis of the cyclic group to the path-shaped flock.

For $s \geq 1$, we diagonalize the matrix $P_j^s = \mathbf{1}\pi^T + Q_j^s$, with,¹³ by (9),

$$Q_j^s = \sum_{k=2}^{2^j} \lambda_k^s C_j^{1/2} v_k v_k^T C_j^{-1/2}, \quad (83)$$

where the right eigenvector $C_j^{1/2} v_k$ is proportional to u_k with the normalization condition, $\|v_k\|_2 = 1$. By elementary trigonometry, it follows that, for any $1 < k \leq 2^j$,

$$\begin{cases} \lambda_k = \frac{1}{3} + \frac{2}{3} \cos \frac{\pi(k-1)}{2^j-1}, \\ v_k = \delta_k \left(\frac{1}{\sqrt{2}}, \cos \frac{\pi(k-1)}{2^j-1}, \dots, \cos \frac{\pi(k-1)(2^j-2)}{2^j-1}, \frac{(-1)^{k-1}}{\sqrt{2}} \right)^T, \end{cases}$$

where $\delta_k = \sqrt{2} (2^j - 1)^{-1/2}$ for $1 < k < 2^j$ and $\delta_{2^j} = (2^j - 1)^{-1/2}$. Recall that $\theta_j = t_{j+1} - t_j$ is the lifetime of the flock F_{a_j} . By the triangle inequality and the submultiplicativity of the Frobenius norm, for any z ,

$$\begin{aligned} \|Q_j^s z\|_2 &\leq |\lambda_2|^s \sum_{k>1} \|C_j^{1/2} v_k v_k^T C_j^{-1/2} z\|_2 \leq |\lambda_2|^s \sum_{k>1} \|C_j^{1/2}\|_F \|C_j^{-1/2}\|_F \|z\|_2 \\ &\leq 2^{j+1} \left| \frac{1}{3} + \frac{2}{3} \cos \frac{\pi}{2^j-1} \right|^s \|z\|_2. \end{aligned}$$

A Taylor series approximation shows that, for $j, s \geq 1$ and any z ,

$$\|Q_j^s z\|_2 \leq e^{j+1-\Omega(s4^{-j})} \|z\|_2. \quad (84)$$

¹³We avoid decorating π and $\mathbf{1}$ with subscripts when their dimensionality is obvious from the context. We use v_k instead of the notation u_k from §3.2. One should be careful not to confuse these eigenvectors with the velocities.

Figure 25: The spectrum of two colliding flocks: to produce a tower-of-twos, the first Fourier coefficients must cancel each other and be replaced by a linear combination of the higher ones. This spectral shift must ensure that the new first Fourier coefficient is nonzero. This will automatically produce an exponentially decaying energy spectrum.

Spectral Shift as Energy Transfer. After s steps following its creation, the flock F_j moves with velocity

$$v^{a_j}(s) = P_j^s v^{a_j} = \mathbf{m}_{a_j} \mathbf{1} + \sum_{k=2}^{2^j} \alpha_k(s) C_j^{1/2} v_k,$$

where $\alpha_k(s) = \lambda_k^s v_k^T C_j^{-1/2} v^{a_j}$. For $k > 1$, the Fourier coefficients $\alpha_k(s)$ decay exponentially fast with s while the first one, the stationary velocity, remains constant. What happens when another flock G_j “collides” with F_j ? A tower-of-twos growth requires two events: one is that, within the algebraic expressions defining the new Fourier coefficients, the stationary velocities should cancel out; the other is that the new first Fourier coefficients should not be zero. For example, consider a flock G_j that is mirror image to F_j and heads straight toward it. The two stationary velocities would cancel out, but the new one would also be zero. Restoring the dimension Y would produce the spectrum on the left in Figure 26 and, consequently, a vertical flying direction: this would dash any hope of achieving a tower-of-twos.

The trick is to ensure that the energy contained in the higher Fourier coefficients averages out in a way that produces a new stationary velocity that is *nonzero*: in two dimensions, this will create a direction close to vertical but not exactly so (right spectrum in the figure). The spectral shift can be viewed as a transfer of energy from the k -th Fourier coefficients (for all $k > 1$) to the first one. The issue is not how to produce exponentially fast decay but how to transfer strictly positive energy. Too much symmetry wipes out all the energy in the first Fourier coefficient, while too little symmetry produces a new stationary velocity

that is a nonzero average of the previous ones. The first case prevents future collisions; the second one produces a new flying direction that deviates from vertical by only a polynomially small angle.

Figure 26: Too much symmetry makes the first Fourier coefficient vanish (left box) and produces a vertical flying direction. Too little symmetry produces an excessive stationary velocity and a polynomially small nonzero angle with the Y direction. The right amount of symmetry produces an energy transfer from the decaying higher Fourier coefficients to the first one, thus creating an exponentially small angle (right box).

The Spectral Shift in Action. Since we are only concerned with velocities in this section, and not with positions, we may assume without loss of generality that all flipping is of the right type: in other words, we stipulate that the flock of any right child of height at least 2 should get its velocity reversed after the prescribed lag time. To restore the true flipping rule will then only be a matter of changing signs appropriately. With this simplifying assumption, the aggregating formula of (73) becomes, for $j > 1$,

$$v^{a_j} = \begin{pmatrix} P_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \\ -P_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \end{pmatrix} = \begin{pmatrix} \mathbf{m}_{a_{j-1}} \mathbf{1} + Q_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \\ -\mathbf{m}_{a_{j-1}} \mathbf{1} - Q_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \end{pmatrix}. \quad (85)$$

The averaging operator P_j cannot increase the maximum absolute value of the velocity coordinates; therefore, by (66),

$$\|v^{a_j}\|_2 \leq 2^{j/2} \|v^{a_j}\|_\infty \leq 2^{j/2} \|v^{a_1}\|_\infty = 2^{j/2} (2n^{-c}).$$

In other words, for any $j \geq 1$,

$$\|v^{a_j}\|_2 \leq 2^{j/2+1} n^{-c}. \quad (86)$$

LEMMA 4.1 For any $j > 1$, the stationary velocity of the flock at node a_j satisfies

$$|\mathbf{m}_{a_j}| \leq e^{-\Omega(\theta_{j-1}4^{-j})}.$$

Proof. The stationary distribution for a 2^{j-1} -bird flock, being a left eigenvector, is normal to the right eigenvectors; hence to $Q_{j-1}^{\theta_{j-1}} v^{a_{j-1}}$. By (64, 85),

$$\begin{aligned} \mathbf{m}_{a_j} &= \frac{1}{2^j - 1} \left(\overbrace{\frac{1}{2}, 1, \dots, 1, \frac{1}{2}}^{2^j} \right) v^{a_j} = \frac{1}{2^j - 1} \left(\overbrace{\frac{1}{2}, 1, \dots, 1, \frac{1}{2}}^{2^j} \right) \begin{pmatrix} Q_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \\ -Q_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \end{pmatrix} \\ &= \frac{1}{2^j - 1} \left(\overbrace{\frac{1}{2}, 1, \dots, 1, \frac{1}{2}}^{2^{j-1}}, \overbrace{\frac{1}{2}, 1, \dots, 1, \frac{1}{2}}^{2^{j-1}} \right) \begin{pmatrix} Q_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \\ -Q_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \end{pmatrix} \\ &\quad + \frac{1}{2^j - 1} \left(\overbrace{0, \dots, 0, \frac{1}{2}, \frac{1}{2}, 0, \dots, 0}^{2^{j-1}}, \overbrace{0, \dots, 0, \frac{1}{2}, \frac{1}{2}, 0, \dots, 0}^{2^{j-1}} \right) \begin{pmatrix} Q_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \\ -Q_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \end{pmatrix} \\ &= \frac{1}{2^{j+1} - 2} \left((Q_{j-1}^{\theta_{j-1}} v^{a_{j-1}})_{2^{j-1}} - (Q_{j-1}^{\theta_{j-1}} v^{a_{j-1}})_1 \right). \end{aligned}$$

By (86), therefore, $\|v^{a_{j-1}}\|_2 \leq 2^{(j+1)/2} n^{-c}$ and, by (84),

$$|\mathbf{m}_{a_j}| \leq \frac{1}{2^j - 1} \left\| Q_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \right\|_\infty \leq \frac{1}{2^j - 1} \left\| Q_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \right\|_2 \leq n^{2-c} e^{-\Omega(\theta_{j-1}4^{-j})}.$$

□

From the spectral decomposition

$$P_j^s v^{a_j} = \mathbf{m}_{a_j} \mathbf{1} + \sum_{k>1} \lambda_k^s C_j^{1/2} v_k v_k^T C_j^{-1/2} v^{a_j},$$

we see that the stationary velocity \mathbf{m}_{a_j} is the first Fourier coefficient, ie, the spectral coordinate associated with the dominant eigenvalue 1. The cancellations of the two copies of $\mathbf{m}_{a_{j-1}}$ in the computation of that coefficient has the effect of making \mathbf{m}_{a_j} a linear combination of powers of higher eigenvalues. That part of the spectrum being exponentially decaying, the corresponding *spectral shift* implies a similar exponential decay in the new first Fourier coefficient. This is the key to the tower-of-twos growth. Indeed, as we show next, the next inter-flock collision cannot occur before a number of steps inversely proportional to that first Fourier coefficient.

LEMMA 4.2 For any $j \geq 1$, $\theta_j = n^f + \Theta(|\mathbf{m}_{a_j}^{-1}|)$.

Proof. By (81), we can assume that $j > 1$. For $t_j < t \leq t_{j+1}$, the velocity of the flock F_{a_j} is of the form

$$\pm P_j^{t-t_j} v^{a_j} = \pm (\mathbf{m}_{a_j} \mathbf{1} + Q_j^{t-t_j} v^{a_j}),$$

where the sign changes after a flip. By (84, 86),

$$\|Q_j^{t-t_j} v^{a_j}\|_2 \leq e^{j+1-\Omega((t-t_j)4^{-j})} \|v^{a_j}\|_2 \leq n^{3-c} e^{-\Omega((t-t_j)n^{-2})}.$$

Summing over all t , our choice of c gives us the conservative upper bound,

$$\sum_{t>t_j} \|Q_j^{t-t_j} v^{a_j}\|_2 \leq \frac{1}{n}.$$

No bird belongs to more than $\log n$ different flocks, so its entire motion is specified by the stationary velocities of its flocks plus or minus an additive “vibration” error of $o(1)$ on the bird’s total displacement.

Until one of them flips, the flock F_{a_j} and the one at its sibling node a'_j are identical copies that have moved in lockstep. The distance between their leftmost birds at time $t_j + n^f$ is what it was at time 0, ie, 2^j . We postpone the integrity analysis for later and simply assume that the flocks are, indeed, single-paths. This implies that the diameter of F_{a_j} is at most $2^j - 1$. By (78), its leftmost edge is of length $\frac{2}{3} \pm o(1)$ between time 0 and t_3 . Since the first two birds always share the same flock, the vibration bound above indicates that they always remain within distance $\frac{2}{3} + o(1)$ of each other. The same bound also shows that, at time $t_j + n^f$, both flocks have diameter at most $2^j - \frac{4}{3} + o(1)$. By our previous observation, they must be at distance at least $\frac{4}{3} - o(1)$. After flipping at time $t_j + n^f$, the two flocks head toward each other¹⁴ at a relative speed of $2|\mathbf{m}_{a_j}|$, plus or minus an error speed that contributes a displacement of $o(1)$. This implies that the time between flipping and merging is $|(6 \pm o(1))\mathbf{m}_{a_j}|^{-1}$. \square

For $j > 1$, we find from Lemmas 4.1 and 4.2 that

$$\theta_j \geq \Omega(e^{\Omega(\theta_{j-1}4^{-j})}).$$

Since, by (71), $\theta_1 > n^4$, it follows immediately by induction that, for any $j \geq 1$,

$$\theta_j > n^4 \theta_{j-1}, \tag{87}$$

where, for convenience, we define $\theta_0 = 1$. This allows us to rewrite our previous lower bound in the slightly simpler fashion,

$$\theta_j \geq e^{\Omega(\theta_{j-1}4^{-j})}, \tag{88}$$

for any $j > 1$. Note that the tower-of-twos lower bound on the flocking time follows immediately from (88). Indeed, let $\hat{\theta}_j = \sqrt{\theta_j}$. By (81), $\hat{\theta}_1 > 2$ and, for $j > 1$, $\hat{\theta}_j \geq 2^{\hat{\theta}_{j-1}}$; therefore, when j reaches $\log n - 1$,

$$\theta_j \geq \hat{\theta}_j > 2 \uparrow \uparrow \log \frac{n}{2},$$

¹⁴We must assume that the left flock flies to the right, so as to put it on a collision course with the other one, after flipping. Our argument is symmetric, however, and would work just the same if directions and flip types were reversed.

Figure 27: Two flocks merge after a period inversely proportional to their stationary velocities. For convenience, we temporarily assume that all flips are of right-type and that flocks fly to the right after they are created: these conditions will not always hold.

which establishes the main lower bound of this paper. \square

For future use, we state a weak bound on stationary velocities. By Lemmas 4.1 and 4.2, for $j > 1$,

$$|\mathbf{m}_{a_j}| \leq e^{-\Omega(\theta_{j-1}4^{-j})} \leq e^{-\Omega(|\mathbf{m}_{a_{j-1}}^{-1}|4^{-j})}.$$

By (86), $|\mathbf{m}_{a_j}| = |\pi^T v^{a_j}| \leq \|v^{a_j}\|_\infty \leq \|v^{a_j}\|_2 < n^{1-c}$. It then follows from (66) that

$$|\mathbf{m}_{a_j}| < \begin{cases} n^{-c}; & \text{if } j = 1; \\ n^{-c} |\mathbf{m}_{a_{j-1}}| & \text{if } j > 1. \end{cases} \quad (89)$$

It remains for us to prove that stationary velocities never vanish and that the flocks keep their structural integrity during their lifetimes. Note that the former would not be true if pairs of colliding flocks were mirror images of each other. The proof must demonstrate that the symmetries needed for the spectral shift do not cause more cancellations than needed. But, first, let us see why the flips conform to the noisy model. Both the number of perturbations and their timing fall well within the admissible bounds. The only nontrivial condition to check is that the change in velocity at flip time $t = t_j + n^f$ ($j > 1$) is $\frac{\log t}{t} e^{O(n^3)}$. The ℓ_2 norm of the change is

$$\delta = 2\|P_j^{t-t_j} v^{a_j}\|_2 \leq 2\sqrt{n} \|v^{a_j}\|_2.$$

We prove below (117) that

$$\|v^{a_j}\|_2 \leq 2\sqrt{n} |\mathbf{m}_{a_{j-1}}|.$$

Since $f = 3$, by (87),

$$t = n^f + \theta_1 + \cdots + \theta_{j-1} \leq 2(\theta_{j-1} - n^f);$$

therefore, by Lemma 4.2,

$$\delta \leq 4n|\mathbf{m}_{a_{j-1}}| = \frac{O(n)}{\theta_{j-1} - n^j} = O\left(\frac{n}{t}\right) \leq \frac{\log t}{t} e^{O(n^3)},$$

which establishes the conformity to the noisy model.

To conclude the kinematic analysis, we must prove that no stationary velocity \mathbf{m}_a ever vanishes. This is not entirely obvious in view of all the symmetries in the system: this would happen, for example, if one flock were the mirror image of its sibling.

Nonvanishing Velocities. We need to take a closer look at the dynamics of the system to show that flocks never grind to a halt. In doing so, we will uncover an iterated process of period 4 that allows us to give a full description of the velocity vector at any time. Again, we assume that all flipping is of type “right,” which affects only the flocks at right children of height at least 2.

THEOREM 4.3 *For any $j \geq 1$, the stationary velocity \mathbf{m}_{a_j} never vanishes. Its direction is such that sibling flocks head toward each other to form bigger flocks.*

Proof. For $j \geq 1$, define the 2^j -by- 2^{j-1} matrix

$$F_j = P_j^{\theta_j} \left(\begin{pmatrix} 1 \\ -1 \end{pmatrix} \otimes I_{2^{j-1}} \right).$$

We form F_j by subtracting the right half of $P_j^{\theta_j}$ from its left half:

$$(F_j)_{k,l} = (P_j^{\theta_j})_{k,l} - (P_j^{\theta_j})_{k,l+2^{j-1}}.$$

For example, if $j = 3$ and $\theta_j = 1$,

$$F_j = \frac{1}{3} \begin{pmatrix} 1 & 2 & 0 & 0 \\ 1 & 1 & 1 & 0 \\ 0 & 1 & 1 & 1 \\ -1 & 0 & 1 & 1 \\ -1 & -1 & 0 & 1 \\ -1 & -1 & -1 & 0 \\ 0 & -1 & -1 & -1 \\ 0 & 0 & -2 & -1 \end{pmatrix}.$$

By (85), for $j > 1$,

$$v^{a_j} = \begin{pmatrix} P_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \\ -P_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \end{pmatrix}$$

and, at the end of its existence, the flock at a_j has velocity (with right flips only):

$$P_j^{\theta_j} v^{a_j} = P_j^{\theta_j} \begin{pmatrix} P_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \\ -P_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \end{pmatrix} = F_j P_{j-1}^{\theta_{j-1}} v^{a_{j-1}} = \left(\prod_{i=j}^2 F_i \right) P_1^{\theta_1} v^{a_1}. \quad (90)$$

Note that indices run *down*, as the products are not commutative. By (64), for $j > 1$,

$$\begin{aligned} \mathbf{m}_{a_j} &= \frac{1}{2^j - 1} \overbrace{\left(\frac{1}{2}, 1, \dots, 1, \frac{1}{2} \right)}^{2^j} \begin{pmatrix} P_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \\ -P_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \end{pmatrix} \\ &= \frac{1}{2(1 - 2^j)} \overbrace{\left(1, 0, \dots, 0, 1 \right)}^{2^j} \begin{pmatrix} P_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \\ -P_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \end{pmatrix} \\ &= \frac{1}{2(1 - 2^j)} \overbrace{\left(1, 0, \dots, 0, 1 \right)}^{2^j} \begin{pmatrix} \left(\prod_{i=j-1}^2 F_i \right) P_1^{\theta_1} v^{a_1} \\ - \left(\prod_{i=j-1}^2 F_i \right) P_1^{\theta_1} v^{a_1} \end{pmatrix} \\ &= \frac{1}{2(1 - 2^j)} z_{j-1,1}^T \left(\prod_{i=j-1}^2 F_i \right) P_1^{\theta_1} v^{a_1}, \end{aligned} \quad (91)$$

where $\prod_i = 1$ if $j = 2$ and

$$z_{j,k} = \overbrace{\left(1, 0, \dots, 0, (-1)^k \right)}^{2^j}{}^T.$$

We now look more closely at the structure of F_j , going back to the spectral decomposition of $P_j^{\theta_j}$. By (83), for $j \geq 1$,

$$\begin{cases} P_j^{\theta_j} = \mathbf{1}_{2^j} \pi^T + Q_j^{\theta_j}, \\ Q_j^{\theta_j} = \sum_{k=2}^{2^j} \mu_{j,k} u_{j,k} \left(u_{j,k} - \frac{1}{2} z_{j,k-1} \right)^T, \end{cases} \quad (92)$$

where, for notational convenience, we subscript **1** to indicate its dimension; for any $j \geq 1$ and $1 < k \leq 2^j$,

$$\begin{cases} \mu_{j,k} = \frac{\varepsilon_{j,k}}{2^j - 1} \left(\frac{1}{3} + \frac{2}{3} \cos \frac{\pi(k-1)}{2^j - 1} \right)^{\theta_j}, \text{ with } \varepsilon_{j,k} = 2 \text{ if } k < 2^j \text{ and } \varepsilon_{j,2^j} = 1; \\ u_{j,k} = \left(1, \cos \frac{\pi(k-1)}{2^j - 1}, \dots, \cos \frac{\pi(k-1)(2^j - 2)}{2^j - 1}, (-1)^{k-1} \right)^T \in \mathbb{R}^{2^j}. \end{cases} \quad (93)$$

Our algebraic approach requires bounds on eigenvalue gaps and on the Frobenius norm of $Q_j^{\theta_j}$. Note that $|\mu_{j,k}| < 1$ for all $j \geq 1$ and $k \geq 2$. We need much tighter bounds. Recall that n is assumed large enough and define $\mu_{0,2} = 1$ for notational convenience.

LEMMA 4.4 For any $j \geq 1$, both $|\mu_{j,2}/\mu_{j-1,2}^n|$ and $\|Q_j^{\theta_j}\|_F$ are less than $e^{-n^{1.5}}$; for $j > 1$ and $k > 2$, so is the ratio $|\mu_{j,k}/\mu_{j,2}|$.

Proof. We leave the bound on $\|Q_j^{\theta_j}\|_F$ for last. If $j = 1$, then $\mu_{j,2} = (-3)^{-\theta_1}$ and, by (87), $|\mu_{j,2}| < e^{-n^4}$. Since $\mu_{0,2} = 1$, this proves the first upper bound for $j = 1$. Suppose now that $j > 1$. For $2 \leq k \leq 2^j$, $|1 + 2 \cos \frac{\pi(k-1)}{2^j-1}| \leq |1 + 2 \cos \frac{\pi}{2^j-1}|$. In view of the fact that $j \leq \log n$ and, by (87), $\theta_j > n^4$, for all $k \geq 2$,

$$|\mu_{j,k}| \leq |\mu_{j,2}| \leq O(2^{-j})e^{-\Omega(\theta_j 4^{-j})} < e^{-n^{1.7}}. \quad (94)$$

By (87),

$$|\mu_{j,2}| \leq e^{-\Omega(\theta_j 4^{-j})} \leq e^{-\Omega(n^4 \theta_{j-1} 4^{-j})} \leq e^{-\Omega(n^2)} e^{-\Omega(n^2 \theta_{j-1})} < e^{-n^{1.5}} |\mu_{j-1,2}|^n.$$

The last inequality follows from the fact that $2^{1-j} 3^{-\theta_{j-1}} \leq |\mu_{j-1,2}| < 1$. To bound the ratio $|\mu_{j,k}/\mu_{j,2}|$ for $j > 1$ and $k > 2$, we begin with the case $j = 2$ and verify directly that e^{-n^3} is a valid upper bound. Indeed,

$$\mu_{2,k} = \begin{cases} (\frac{2}{3})^{\theta_2+1} & \text{if } k = 2; \\ 0 & \text{if } k = 3; \\ (-1)^{\theta_2} (\frac{1}{3})^{\theta_2+1} & \text{if } k = 4. \end{cases}$$

Assume now that $j, k > 2$. Then $-1 \leq 1 + 2 \cos \frac{\pi(k-1)}{2^j-1} \leq 1 + 2 \cos \frac{2\pi}{2^j-1}$. Since $1 + 2 \cos \frac{2\pi}{2^j-1} > 1$, $|1 + 2 \cos \frac{\pi(k-1)}{2^j-1}| \leq |1 + 2 \cos \frac{2\pi}{2^j-1}|$; therefore,

$$\left| \frac{\mu_{j,k}}{\mu_{j,2}} \right| \leq \left(\frac{1 + 2 \cos \frac{2\pi}{2^j-1}}{1 + 2 \cos \frac{\pi}{2^j-1}} \right)^{\theta_j} = (2 \cos \frac{\pi}{2^j-1} - 1)^{\theta_j} = e^{-\Omega(\theta_j 4^{-j})} < e^{-n^{1.5}}.$$

For all $j \geq 1$, by (94) and the submultiplicativity of the Frobenius norm,

$$\begin{aligned} \|Q_j^{\theta_j}\|_F &\leq \sum_{k=2}^{2^j} |\mu_{j,k}| \times \|u_{j,k}\|_2 (\|u_{j,k}\|_2 + \frac{1}{2} \|z_{j,k-1}\|_2) \\ &\leq 2^{O(j)} |\mu_{j,2}| \leq 2^{O(j)} e^{-n^{1.7}} < e^{-n^{1.5}}. \end{aligned}$$

□

For $j > 1$, we express F_j , the ‘‘folded’’ half of $P_j^{\theta_j}$, by subtracting the lower half of $u_{j,k} - \frac{1}{2} z_{j,k-1}$ from its upper half, forming

$$w_{j-1,k} = (\xi_1, \dots, \xi_{2^{j-1}})^T - \frac{1}{2} z_{j-1,k}, \quad (95)$$

where

$$\xi_l = \cos \frac{\pi(k-1)(l-1)}{2^j-1} - \cos \frac{\pi(k-1)(2^{j-1}+l-1)}{2^j-1}.$$

It follows from (82, 92) that, for $j > 1$,

$$F_j = \frac{1}{2(1-2^j)} \mathbf{1}_{2^j} z_{j-1,1}^T + \sum_{k=2}^{2^j} \mu_{j,k} u_{j,k} w_{j-1,k}^T. \quad (96)$$

To tackle the formidable product $\prod_i F_i$ in (90), we begin with an approximation $\prod_i G_i$, where

$$G_j = \frac{1}{2(1-2^j)} \mathbf{1}_{2^j} z_{j-1,1}^T + \mu_{j,2} u_{j,2} w_{j-1,2}^T. \quad (97)$$

Setting $k = 2$, we find that

$$u_{j,2} = \left(1, \cos \frac{\pi}{2^{j-1}}, \dots, \cos \frac{\pi(2^j-2)}{2^{j-1}}, -1 \right)^T.$$

For $0 \leq l < 2^{j-1}$,

$$\cos \frac{\pi l}{2^{j-1}} + \cos \frac{\pi(2^j-l-1)}{2^{j-1}} = 0.$$

This extends to the case $j = 1$, so that, for any $j \geq 1$,

$$\begin{cases} u_{j,2} = (\bar{u}_1, \dots, \bar{u}_{2^{j-1}}, -\bar{u}_{2^{j-1}}, \dots, -\bar{u}_1)^T; \\ \bar{u}_l = \cos \frac{\pi(l-1)}{2^{j-1}}. \end{cases} \quad (98)$$

For $k = 2$, we simplify ξ_l into

$$\xi_l = \cos \frac{\pi(l-1)}{2^{j-1}} + \sin \frac{\pi(l-\frac{1}{2})}{2^{j-1}},$$

for $1 \leq l \leq 2^{j-1}$, which shows that $\xi_l = \xi_{2^{j-1}+1-l}$; therefore, for $j > 1$,

$$\begin{cases} w_{j-1,2} = (\bar{w}_1, \dots, \bar{w}_{2^{j-2}}, \bar{w}_{2^{j-2}}, \dots, \bar{w}_1)^T; \\ \bar{w}_1 = \frac{1}{2} + \sin \frac{\pi/2}{2^{j-1}}; \\ \bar{w}_l = \cos \frac{\pi(l-1)}{2^{j-1}} + \sin \frac{\pi(l-\frac{1}{2})}{2^{j-1}} \quad (1 < l \leq 2^{j-2}). \end{cases} \quad (99)$$

By (97), for $j > 2$,

$$\prod_{i=j-1}^2 G_i = \prod_{i=j-1}^2 \left\{ \frac{1}{2(1-2^i)} \mathbf{1}_{2^i} z_{i-1,1}^T + \mu_{i,2} u_{i,2} w_{i-1,2}^T \right\}. \quad (100)$$

Expanding this product is greatly simplified by observing that, by (98, 99), for any $j \geq 1$,

$$\begin{cases} z_{j,1}^T \mathbf{1}_{2^j} = w_{j,2}^T u_{j,2} = 0; \\ z_{j,1}^T u_{j,2} = 2; \\ w_{j,2}^T \mathbf{1}_{2^j} \stackrel{\text{def}}{=} \gamma_j, \quad \text{where } 2^{j-1} - 1 < \gamma_j < 2^{j+1} - 1. \end{cases} \quad (101)$$

To prove the bounds on γ_j , we rely on (99),

$$\gamma_j = -1 + 2 \sum_{l=1}^{2^{j-1}} \left(\cos \frac{\pi(l-1)}{2^{j+1}-1} + \sin \frac{\pi(l-\frac{1}{2})}{2^{j+1}-1} \right),$$

and the fact that $\frac{\pi(l-1)}{2^{j+1}-1} \leq \frac{\pi}{3}$ and $\frac{\pi(l-1/2)}{2^{j+1}-1} < \frac{\pi}{2}$, from which the two inequalities in (101) follow readily. By (100), for $j > 2$,

$$\begin{aligned} z_{j-1,1}^T \left(\prod_{i=j-1}^2 G_i \right) P_1^{\theta_1} v^{a_1} \\ = z_{j-1,1}^T \left(\prod_{i=j-1}^2 \left\{ \frac{1}{2(1-2^i)} \mathbf{1}_{2^i} z_{i-1,1}^T + \mu_{i,2} u_{i,2} w_{i-1,2}^T \right\} \right) P_1^{\theta_1} v^{a_1}. \end{aligned} \quad (102)$$

If we drop all sub/superscripts and expand the scalar expression above, we find a sum of 2^{j-2} words $z a_{j-1} \cdots a_2 P_1^{\theta_1} v^{a_1}$, where each a_i is of the form $\mu u w$ or $1z$ (suitably scaled). By (101), however, the only nonzero word is of the form $A = z(\mu u w)(1z)(\mu u w)(1z) \cdots P_1^{\theta_1} v^{a_1}$. This necessitates distinguishing between even and odd values of j .

Figure 28: If j is odd, the word A is of the form $z(\mu u w)(1z)(\mu u w)(1z) \cdots (\mu u w) P_1^{\theta_1} v^{a_1}$.

Case I. (*odd* $j > 2$): It follows from (101) that

$$\begin{aligned} z_{j-1,1}^T \left(\prod_{i=j-1}^2 G_i \right) \\ = z_{j-1,1}^T \mu_{j-1,2} u_{j-1,2} w_{j-2,2}^T \prod_{\text{odd } i=j-2}^3 \left\{ \frac{1}{2(1-2^i)} \mathbf{1}_{2^i} z_{i-1,1}^T \mu_{i-1,2} u_{i-1,2} w_{i-2,2}^T \right\} \\ = 2 \mu_{j-1,2} w_{j-2,2}^T \prod_{\text{odd } i=j-2}^3 \left\{ \frac{1}{1-2^i} \mathbf{1}_{2^i} \mu_{i-1,2} w_{i-2,2}^T \right\} = \alpha_j^{\text{odd}} w_{1,2}^T, \end{aligned}$$

where

$$\alpha_j^{odd} = 2(-1)^{(j+1)/2} \mu_{2,2} \prod_{\text{odd } i=j-2}^3 \frac{\gamma_i \mu_{i+1,2}}{2^i - 1}. \quad (103)$$

One must verify separately that this also holds for the case $j = 3$, where $\prod_i = 1$. Recall that, by (66, 99), $w_{1,2} = (1, 1)^T$ and $\|v^{a_1}\|_2 = \sqrt{5} n^{-c}$. By Lemma 4.4 and the submultiplicativity of the Frobenius norm,

$$|w_{1,2}^T Q_1^{\theta_1} v^{a_1}| \leq \|w_{1,2}\|_2 \|Q_1^{\theta_1}\|_F \|v^{a_1}\|_2 < e^{-n^{1.5}}.$$

By (92), it follows that

$$w_{1,2}^T P_1^{\theta_1} v^{a_1} = w_{1,2}^T (\mathbf{1}_2 \pi^T + Q_1^{\theta_1}) v^{a_1} = v_1^{a_1} + v_2^{a_1} \pm O(e^{-n^{1.5}}) \quad (104)$$

and

$$\begin{aligned} A &= z_{j-1,1}^T \left(\prod_{i=j-1}^2 G_i \right) P_1^{\theta_1} v^{a_1} = \alpha_j^{odd} w_{1,2}^T P_1^{\theta_1} v^{a_1} \\ &= \alpha_j^{odd} (v_1^{a_1} + v_2^{a_1}) \pm O(\alpha_j^{odd} e^{-n^{1.5}}). \end{aligned} \quad (105)$$

Figure 29: If j is even, the word A is of the form $z(\mu w)(1z)(\mu w) \cdots (1z) P_1^{\theta_1} v^{a_1}$.

Case II. (even $j > 2$):

$$\begin{aligned} z_{j-1,1}^T \left(\prod_{i=j-1}^2 G_i \right) &= z_{j-1,1}^T \prod_{\text{odd } i=j-1}^3 \left\{ \mu_{i,2} u_{i,2} w_{i-1,2}^T \left(\frac{1}{2(1-2^{i-1})} \right) \mathbf{1}_{2^{i-1}} z_{i-2,1}^T \right\} \\ &= z_{j-1,1}^T \prod_{\text{odd } i=j-1}^3 \left\{ \left(\frac{1}{2(1-2^{i-1})} \right) \mu_{i,2} u_{i,2} \gamma_{i-1} z_{i-2,1}^T \right\} = \beta_j z_{1,1}^T, \end{aligned}$$

where

$$\beta_j = (-1)^{j/2+1} \prod_{\text{odd } i=j-1}^3 \frac{\gamma_{i-1}\mu_{i,2}}{2^{i-1}-1}.$$

It follows that

$$A = z_{j-1,1}^T \left(\prod_{i=j-1}^2 G_i \right) P_1^{\theta_1} v^{a_1} = \beta_j z_{1,1}^T P_1^{\theta_1} v^{a_1}.$$

By (92),

$$z_{1,1}^T P_1^{\theta_1} v^{a_1} = z_{1,1}^T (\mathbf{1}_2 \pi^T + Q_1^{\theta_1}) v^{a_1} = z_{1,1}^T Q_1^{\theta_1} v^{a_1} = \mu_{1,2} (v_1^{a_1} - v_2^{a_1}); \quad (106)$$

therefore,

$$A = \alpha_j^{\text{even}} (v_1^{a_1} - v_2^{a_1}), \quad (107)$$

where

$$\alpha_j^{\text{even}} = (-1)^{j/2+1} \mu_{1,2} \prod_{\text{odd } i=j-1}^3 \frac{\gamma_{i-1}\mu_{i,2}}{2^{i-1}-1}. \quad (108)$$

This concludes the case analysis. Next, we still assume that $j > 2$ but we remove all restriction on parity. Recall that G_i is only an approximation of F_i and, instead of (102), we must contend with

$$\begin{aligned} & z_{j-1,1}^T \left(\prod_{i=j-1}^2 F_i \right) P_1^{\theta_1} v^{a_1} \\ &= z_{j-1,1}^T \left(\prod_{i=j-1}^2 \left\{ \frac{1}{2(1-2^i)} \mathbf{1}_{2^i} z_{i-1,1}^T + \sum_{k=2}^{2^i} \mu_{i,k} u_{i,k} w_{i-1,k}^T \right\} \right) P_1^{\theta_1} v^{a_1}. \end{aligned} \quad (109)$$

If, again, we look at the expansion of the product as a sum of words

$$B = z a_{j-1} \cdots a_2 P_1^{\theta_1} v^{a_1},$$

then we see that each B -word is the form

$$z(\mu u w) \{1z, \mu u w\} \{1z, \mu u w\} \{1z, \mu u w\} \cdots P_1^{\theta_1} v^{a_1},$$

where μ, u, w are now indexed by k . Recall that previously the only word was of the form $A = z(\mu u w)(1z)(\mu u w)(1z) \cdots P_1^{\theta_1} v^{a_1}$. There is no need to go over the entire analysis again. By showing that $|B|$ is always much smaller than $|A|$, we prove

LEMMA 4.5 *For any $2 < j \leq \log n$,*

$$z_{j-1,1}^T \left(\prod_{i=j-1}^2 F_i \right) P_1^{\theta_1} v^{a_1} = \begin{cases} (1 + \varepsilon_n)(v_1^{a_1} + v_2^{a_1}) \alpha_j^{\text{odd}} & \text{if } j \text{ is odd;} \\ (1 + \varepsilon'_n)(v_1^{a_1} - v_2^{a_1}) \alpha_j^{\text{even}} & \text{else,} \end{cases}$$

where $\varepsilon_n, \varepsilon'_n$ are reals of absolute value $O(e^{-n})$.

Proof. Note that, by (101), $\gamma_i > 2^{i-1} - 1$ for any $i \geq 1$. Also, by (66), $v_1^{a_1} + v_2^{a_1} = n^{-c}$ and $v_2^{a_1} - v_1^{a_1} = 3n^{-c}$. It follows from (103, 105, 107, 108) that, for any $2 < j \leq \log n$,

$$|A| = \left| z_{j-1,1}^T \left(\prod_{i=j-1}^2 G_i \right) P_1^{\theta_1} v^{a_1} \right| \geq \left(\frac{1}{n} \right)^{c+1} \begin{cases} |\mu_{2,2} \mu_{4,2} \cdots \mu_{j-1,2}| & \text{if } j \text{ is odd;} \\ |\mu_{1,2} \mu_{3,2} \cdots \mu_{j-1,2}| & \text{else.} \end{cases} \quad (110)$$

We take absolute values on the right-hand side for notational consistency: all the factors, defined in (93), are strictly positive, except for $\mu_{1,2} = (-3)^{-\theta_1}$ which, by (71), is equal to $-3^{-\theta_1} < 0$, ie, for $i > 1$,

$$\mu_{1,2} < 0 < \mu_{i,2}. \quad (111)$$

Let's extend our notation by defining, for $i > 1$,

$$\begin{cases} \mu_{i,1} = \frac{1}{2}(1 - 2^i)^{-1}; \\ u_{i,1} = \mathbf{1}_{2^i}; \\ w_{i-1,1} = z_{i-1,1}. \end{cases}$$

Then, any B -word is specified by an index vector (k_{j-1}, \dots, k_2) :

$$B_{k_{j-1}, \dots, k_2} = w_{j-1,1}^T \left(\prod_{i=j-1}^2 \mu_{i,k_i} u_{i,k_i} w_{i-1,k_i}^T \right) P_1^{\theta_1} v^{a_1}.$$

Observe that the A -word we considered earlier is a particular B -word, ie,

$$A = B_{\underbrace{2,1,2,1,\dots}_{j-2}}.$$

Since we wish to show that all the other B -words are considerably smaller, we may ignore the settings of k_i that make a B -word vanish. All the conditions on the index vector are summarized here:

$$\begin{cases} 1 \leq k_i \leq 2^i; \\ k_{j-1} \neq 1; \\ k_i k_{i-1} \neq 1 \quad (2 < i < j). \end{cases} \quad (112)$$

By (93, 95), for all $i > 1$ and $k \geq 1$, $\|u_{i,k}\|_2 \leq 2^{i/2}$ and for $i, k \geq 1$, $\|w_{i,k}\|_2 \leq 2^{i/2+2}$; so, by Cauchy-Schwarz, for $i > 2$ and $k, l \geq 1$,

$$|w_{i-1,k}^T u_{i-1,l}| \leq 2^{i+1}.$$

Since $2 < j \leq \log n$,

$$\left| w_{j-1,1}^T u_{j-1,k_{j-1}} \prod_{i=j-2}^2 w_{i,k_{i+1}}^T u_{i,k_i} \right| \leq 2^{\frac{1}{2}(j+1)(j+2)} < n^{2 \log n},$$

therefore,

$$|B_{k_{j-1}, \dots, k_2}| \leq n^{2 \log n} \left(\prod_{i=j-1}^2 \mu_{i,k_i} \right) |w_{1,k_2}^T P_1^{\theta_1} v^{a_1}|. \quad (113)$$

We prove that all B -words are much smaller than A in absolute value.

LEMMA 4.6. *All B -words distinct from A satisfy:*

$$|B_{k_{j-1}, \dots, k_2}| < e^{-n^{1.2}} |A|.$$

Proof. Since P_1 is stochastic, by (66),

$$|w_{1,k_2}^T P_1^{\theta_1} v^{a_1}| = O(\|v^{a_1}\|_\infty) = O(n^{-c}) < 1,$$

and the upper bound (113) becomes

$$|B_{k_{j-1}, \dots, k_2}| \leq n^{2 \log n} \prod_{i=j-1}^2 \mu_{i,k_i}. \quad (114)$$

To maximize the right-hand side of (114), we may replace any instance of $k_i > 2$ by $k_i = 2$ (Lemma 4.4). This does not contradict conditions (112) since no index is set to 1. Note the importance for this step of having removed all vectorial presence from (114). We assume that the new B -word is not A , so its index vector is not of the form $(2, 1, 2, 1, \dots)$; therefore, if we end up with this very pattern, and hence with A , obviously at least one index replacement must have taken place. By Lemma 4.4, any such replacement causes an increase by a factor of at least $e^{n^{1.5}}$ and Lemma 4.6 follows. So, we may assume now that $k_i \in \{1, 2\}$ and

$$(k_{j-1}, k_{j-2}, \dots, k_2) \neq (2, 1, 2, 1, \dots).$$

Scan the string (k_{j-1}, \dots, k_2) against $(2, 1, 2, 1, \dots)$ from left to right and let k_a be the first character that differs. By (112), $k_{j-1} = 2$, so $2 \leq a \leq j-2$; hence $j > 3$. Since we cannot have consecutive ones, $k_a = 2$ and $j-a$ is even. By (110) and Lemma 4.4,

$$\begin{aligned} \frac{|B_{k_{j-1}, \dots, k_2}|}{|A|} &\leq (n^{c+1} n^{2 \log n}) \frac{|\mu_{j-1,2} \mu_{j-2,1} \mu_{j-3,2} \cdots \mu_{a+1,2} \mu_{a,2} \mu_{a-1,k_{a-1}} \cdots \mu_{2,k_2}|}{|\mu_{j-1,2} \mu_{j-3,2} \cdots \mu_{a+1,2} \mu_{a-1,2} \mu_{a-3,2} \cdots|} \\ &\leq n^{3 \log n} \frac{|\mu_{j-2,1} \mu_{j-4,1} \cdots \mu_{a+2,1} \mu_{a,2} \mu_{a-1,k_{a-1}} \cdots \mu_{2,k_2}|}{|\mu_{a-1,2} \mu_{a-3,2} \cdots|}. \end{aligned}$$

Figure 30: The top horizontal line represents $k_i = 1$. The white dots below the line correspond to $k_i = 2$. The B -word in white is brought into canonical form (black jagged line) by setting all the indices $k_i > 2$ to 2. This cannot cause the magnitude of B to drop. We may also assume that the end result is not the A -word, as this would cause an exponential growth in line with the lemma.

The first numerator mirrors the index vector of the B -word accurately. For the denominator, however, we use the lower bound of (110). The reason we can afford such a loose estimate is the presence of the factor $\mu_{a,2}$, which plays the central role in the calculation by drowning out all the other differences. Here are the details. All μ 's are less than 1 and, by Lemma 4.4, $|\mu_{a-1,2}| \leq |\mu_{a-l,2}|$; therefore,

$$\frac{|B_{k_{j-1}, \dots, k_2}|}{|A|} \leq n^{3 \log n} \frac{|\mu_{a,2}|}{|\mu_{a-1,2}^{\log n}|} < n^{3 \log n} \frac{|\mu_{a,2}|}{|\mu_{a-1,2}^n|} < n^{3 \log n} e^{-n^{1.5}}.$$

which proves Lemma 4.6. \square

There are fewer than $n^{\log n}$ B -words; so, by Lemma 4.6, their total contribution amounts to at most a fraction $n^{\log n} e^{-n^{1.2}}$ of $|A|$. In other words, by (109), for $j > 2$,

$$z_{j-1,1}^T \left(\prod_{i=j-1}^2 F_i \right) P_1^{\theta_1} v^{a_1} = (1 \pm O(e^{-n})) z_{j-1,1}^T \left(\prod_{i=j-1}^2 G_i \right) P_1^{\theta_1} v^{a_1},$$

and the proof of Lemma 4.5 follows from (66, 105, 107). \square

Recall from (91) that, for $j > 1$,

$$\mathbf{m}_{a_j} = \frac{1}{2(1-2^j)} z_{j-1,1}^T \left(\prod_{i=j-1}^2 F_i \right) P_1^{\theta_1} v^{a_1}.$$

Figure 31: We trace the index vectors of the A and B -words from left to right until they diverge ($i = a$). In this case, j is odd and the index vector of the B -word is $(2, 1, 2, 1, 2, 2, 1, 2, 2)$.

We know from (101, 103, 108, 111) that neither α_j^{even} nor α_j^{odd} is null. By Lemma 4.5, it then follows that the stationary velocity \mathbf{m}_{a_j} never vanishes for $j > 2$. By (66, 74), this is also the case for $j = 1, 2$. To be nonnull is not enough, however: sibling flocks must also head toward each other. This is what the flipping rule ensures. We next show how.

Drifting Direction. By (66, 74), $\mathbf{m}_{a_2} < 0 < \mathbf{m}_{a_1}$. By Lemma 4.5, for $j > 2$,

$$\mathbf{m}_{a_j} = \frac{1}{2(1-2^j)} \begin{cases} (1 + \varepsilon_n)(v_1^{a_1} + v_2^{a_1})\alpha_j^{odd} & \text{if } j \text{ is odd;} \\ (1 + \varepsilon'_n)(v_1^{a_1} - v_2^{a_1})\alpha_j^{even} & \text{else.} \end{cases} \quad (115)$$

We observed in (111) that $\mu_{j,2}$ is positive for all $j \geq 1$, with the exception of $\mu_{1,2} < 0$. By (103), the sign of α_j^{odd} is that of $(-1)^{(j+1)/2}$. On the other hand, by (108), the sign of α_j^{even} is that of $(-1)^{j/2}$. By (66), this proves that, for $j > 0$, the sign of \mathbf{m}_{a_j} is positive if and only if $j = 0, 1 \pmod{4}$. Remember that this is what happens when all the flips are confined to the right children of height $j \geq 2$, what we called right-type flips. The actual rule is more complex. It applies to flocks at left children of nodes of odd height at least 3 and to flocks at right children of nodes of even height at least 4. We verify that, after the appropriate flip, if any, every \mathbf{m}_{a_j} is positive, ie, all the flocks along the left spine of the fusion tree \mathcal{T} drift to the right, as they should. But, before we show this, let's convince ourselves that right-type flips alone would not do: indeed, note that $\mathbf{m}_{a_2} < 0$, so a right-type flip for the right child of a_3 would send the two flocks flying away from each other (Figure 32).

Here is a quick proof of the soundness of the true flipping rule. Suppose we follow the right-type rule. How do we then modify the velocities to end up with the same sign assignment produced by the true flipping rule? The answer is simple: reverse the sign of the velocities of the flocks at both children of nodes of odd height at least 3. For $j \geq 2$, the velocity of the flock at a_j will be effectively reversed a number of times equal to $\lfloor (j-1)/2 \rfloor$. The velocity is effectively changed

Figure 32: A right-type flip would make the two 4-bird flocks drift away from each other.

only when that number is odd, ie, when $j = 0, 3 \pmod{4}$. Recall that $\mathbf{m}_{a_j} > 0$ if $j = 0, 1 \pmod{4}$ and $j > 0$. That implies that \mathbf{m}_{a_j} is now positive exactly when $j = 1, 3 \pmod{4}$, ie, j is odd. When j is even, however, the node a_j , being a left child of an odd-height node, undergoes a flip, which therefore reverses its stationary velocity and makes it positive. So, in all cases, \mathbf{m}_{a_j} is either positive or made positive after the lag time for a flip: the corresponding flock is then headed on a collision course with its sibling. Note that, as we observed in the footnote of the proof of Lemma 4.2, our previous analysis leading to the tower-of-twos growth still holds despite the restoration of the true flipping rule. This concludes the proof of Theorem 4.3. \square

It remains for us to establish the structural integrity of the flocks throughout their lifetime. But, before we do so, it is useful to revisit the spectral shift and its parity structure.

The Hidden Periodicity of the Spectral Shift. The formula for the stationary velocity in (115) reveals a built-in periodicity that illustrates a fundamental aspect of the spectral shift. Looking at (110), one may wonder why the second largest eigenvalues all appear with the same index parity: odd when j is even and vice versa. Think of the velocity of a flock as being well approximated by $\sigma \mathbf{1} + \gamma \mathbf{u}$, where σ is the speed of its drift and $\gamma \mathbf{u}$ is its *vibration* vector pointing in the direction of the second right eigenvector scaled by a Fourier coefficient γ decaying exponentially fast with time. Take the time to be right before merging with the flock's sibling. Then the velocity of the new flock is of the form

$$\begin{pmatrix} \sigma \mathbf{1} + \gamma \mathbf{u} \\ -\sigma \mathbf{1} - \gamma \mathbf{u} \end{pmatrix}.$$

We approximate the transition matrix $P_j^{\theta_j}$ as $\mathbf{1}\pi^T + \mu_{j,2}\mathbf{R}$, where \mathbf{R} is a fixed matrix of rank 1. After θ_j steps, the velocity becomes roughly (ignoring time-

independent factors):

$$(\mathbf{1}\pi^T + \mu_{j,2}\mathbf{R}) \begin{pmatrix} \sigma\mathbf{1} + \gamma\mathbf{u} \\ -\sigma\mathbf{1} - \gamma\mathbf{u} \end{pmatrix} \approx \gamma\mathbf{1} + \sigma\mu_{j,2}\mathbf{w},$$

where \mathbf{w} is a unit vector. We ignore the lower-order term $\mu_{j,2}\gamma$. It thus appears that the pair (σ, γ) becomes $(\gamma, \sigma\mu_{j,2})$ for the bigger flock. Note the alternation between (σ, γ) and (γ, σ) . In particular, the switch of γ from the right to the left position in the pair captures the spectral shift underlying the flocking process, while the contrary motion of σ indicates a re-injection of the first Fourier coefficient into the spectral mix. In general, we have the relation $(\sigma_{j+1}, \gamma_{j+1}) = (\gamma_j, \sigma_j\mu_{j,2})$; hence,

$$(\sigma_{j+2}, \gamma_{j+2}) = (\sigma_j\mu_{j,2}, \gamma_j\mu_{j+1,2}).$$

This shows that $\sigma_{j+2} = (\mu_{j-2,2}\mu_{j,2})\sigma_{j-2}$, which explains the parity-based grouping of (103, 108). Of course, the hard part is to show that none of these terms vanish. Note, in particular, that the vector

$$\mathbf{1}\pi^T \begin{pmatrix} \gamma\mathbf{u} \\ -\gamma\mathbf{u} \end{pmatrix}$$

comes frighteningly close to vanishing. A little bit of symmetry in the wrong place is enough to derail the spectral shift. A uniform stationary distribution, for example, would destroy the entire scheme; so would a vector \mathbf{u} with the same first and last coordinates.

4.3 Integrity Analysis

We saw in Section 4.1 that the flocks of size 2 and 4 remain single paths during their lifetimes. The following result establishes the integrity of all the flocks. Though not stated explicitly, the result also asserts that the birds $\mathcal{B}_1, \dots, \mathcal{B}_n$ always appear in that order from left to right.

THEOREM 4.7 *Any two adjacent birds within the same flock lie at a distance between 0.58 and 1. This holds over the entire lifetime of the flock, whether it flips or not.*

Proof. As is sometimes the case, it is simpler to prove a more complicated bound, from which the theorem follows. For notational convenience, put $\mathbf{m}_{a_0} = \frac{1}{4}n^{-5}$ and define $h(i)$ as the height of the nearest common ancestor of the two leaves associated with \mathcal{B}_i and \mathcal{B}_{i+1} ; eg, $h(1) = 1$ and $h(2) = 2$. We prove by induction on j that, for any $1 \leq j < \log n$, $t_j \leq t \leq t_{j+1}$, and $1 \leq i < 2^j$,

$$\begin{aligned} 1 - \frac{5}{3}(n^5 + jn^4)|\mathbf{m}_{a_{h(i)-1}}| &\leq \text{DIST}_t(\mathcal{B}_i, \mathcal{B}_{i+1}) \\ &\leq \begin{cases} 1 & \text{if } i = 2^{j-1} \text{ and } t = t_j; \\ 1 - \frac{1}{4}(1 - \frac{j}{n})|\mathbf{m}_{a_{h(i)-1}}| & \text{else.} \end{cases} \end{aligned} \quad (116)$$

Recall that a_0, a_1 , etc, constitute the left spine of the fusion tree \mathcal{T} . By (89), the upper and lower bounds above fall between 0.58 and 1, so satisfying them implies the integrity of the flocks along the spine: indeed, the upper bound ensures the existence of the desired edges, while the lower bound greater than $\frac{1}{2}$ rules out edges between nonconsecutive birds. To extend this to all the flocks, and hence prove the theorem, we establish (116) for *nondeterministic* flipping, ie, assuming that any node may or may not flip regardless of what the true flipping rule dictates. The issue here is that the left spine does not represent *all* flocks: reversing velocities changes the positions of birds irreversibly, so technically we should prove (116) not just along the left spine but along *any* path of \mathcal{T} . We can do this all at once by considering both cases, flip and no-flip, at each node a_j .

We proceed by induction on j . Before we get on with the proof, we should explain why the upper bound of (116) distinguishes between two cases. In general, once two consecutive birds are joined in a flock, they stay forever at a distance strictly less than 1. There is only one exception to this rule: at the time t when they join, the only assurance we can give is that their distance does not exceed 1; it could actually be equal to 1, hence the difficulty of a nontrivial upper bound when $t = t_j$ and $i = 2^{j-1}$. The case $j = 1$ is special because two-bird flocks never flip but are provided with two different kinds of initial velocities; therefore, we must check both $(\mathcal{B}_1, \mathcal{B}_2)$ and $(\mathcal{B}_3, \mathcal{B}_4)$. We verify (116) directly from (68, 70). Indeed, for $0 \leq t \leq t_2$,

$$\frac{2}{3} - n^{-c} \leq x_2(t) - x_1(t) \leq x_4(t) - x_3(t) \leq \frac{2}{3} + n^{-c}.$$

Assume now that $j \geq 2$. By applying successively (84, 86), Lemma 4.2, and (89), we find that

$$\begin{aligned} \|Q_{j-1}^{\theta_{j-1}} v^{a_{j-1}}\|_2 &\leq e^{j-\Omega(\theta_{j-1}4^{1-j})} \|v^{a_{j-1}}\|_2 \leq e^{-\Omega(n^{-2}/|\mathbf{m}_{a_{j-1}}|)} \\ &\leq e^{-2n-\Omega(n^{-2}/|\mathbf{m}_{a_{j-1}}|)} < |\mathbf{m}_{a_{j-1}}| e^{-2n}. \end{aligned}$$

By (85),

$$v^{a_j} = \pm \begin{pmatrix} P_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \\ -P_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \end{pmatrix} = |\mathbf{m}_{a_{j-1}}| \begin{pmatrix} 1 \\ -1 \end{pmatrix} \otimes \mathbf{1}_{2^{j-1}} \pm \begin{pmatrix} Q_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \\ -Q_{j-1}^{\theta_{j-1}} v^{a_{j-1}} \end{pmatrix}.$$

The \pm leaves open the possibility of a flip of either type, right or left, before the 2^{j-1} -bird flocks join at time t_j . As we saw earlier, the choice of type ensures that the flock with the lower-indexed birds drifts to the right while its sibling, with the higher-indexed birds, flies to the left; hence the certainty that, after flipping, the “fixed” part of the velocity vector v^{a_j} is of the form $|\mathbf{m}_{a_{j-1}}|(1, -1)^T \otimes \mathbf{1}_{2^{j-1}}$. (In fact, to achieve just this is the sole purpose of flipping.) It follows that

$$v^{a_j} = |\mathbf{m}_{a_{j-1}}| \begin{pmatrix} 1 \\ -1 \end{pmatrix} \otimes \mathbf{1}_{2^{j-1}} + \zeta, \quad \text{with } \|\zeta\|_2 < |\mathbf{m}_{a_{j-1}}| e^{-n}. \quad (117)$$

For $1 \leq i < 2^j$, define

$$\chi_i = \underbrace{(0, \dots, 0, -1, 1, 0, \dots, 0)}_{2^j}^i.$$

By (83), for $s \geq 1$,

$$\chi_i^T P_j^s v^{a_j} = \mathbf{m}_{a_j} \chi_i^T \mathbf{1}_{2^j} + \chi_i^T Q_j^s v^{a_j} = \chi_i^T Q_j^s v^{a_j};$$

hence, for $t_j < t \leq t_{j+1}$,

$$\text{DIST}_t(\mathcal{B}_i, \mathcal{B}_{i+1}) = \text{DIST}_{t_j}(\mathcal{B}_i, \mathcal{B}_{i+1}) + \sum_{s=1}^{t-t_j} (-1)^{f(s)} \chi_i^T Q_j^s v^{a_j}, \quad (118)$$

where $f(s) = 1$ if there is a flip and $s > n^f$, and $f(s) = 0$ otherwise. Note that there is no risk in using $\text{DIST}_t(\mathcal{B}_i, \mathcal{B}_{i+1})$, instead of the signed version, $x_{i+1}(t) - x_i(t)$, that birds might cross unnoticed: indeed, the bound in (86) applies to all the velocities, so that distances cannot change by more than $O(n^{1-c})$ in one step. This implies that a change of sign for $x_{i+1}(t) - x_i(t)$ would be preceded by the drop of $\text{DIST}_t(\mathcal{B}_i, \mathcal{B}_{i+1})$ below $\frac{1}{2}$ and a violation of (116). By Cauchy-Schwarz and (84, 117),

$$|\chi_i^T Q_j^s \zeta| \leq \sqrt{2} \|Q_j^s \zeta\|_2 \leq \sqrt{2} e^{j+1-\Omega(s4^{-j})} \|\zeta\|_2 \leq n^2 e^{-n-\Omega(s/n^2)} |\mathbf{m}_{a_{j-1}}|;$$

and, since n is assumed large enough, for $s \geq 1$,

$$|\chi_i^T Q_j^s \zeta| < e^{-\frac{1}{2}n - sn^{-3}} |\mathbf{m}_{a_{j-1}}|. \quad (119)$$

Likewise,

$$\begin{aligned} |\chi_i^T Q_j^s v^{a_j}| &\leq \sqrt{2} \|Q_j^s v^{a_j}\|_2 \leq n^{1.45} e^{-\Omega(s/n^2)} \|v^{a_j}\|_2 \\ &\leq n^{1.45} e^{-\Omega(s/n^2)} (|\mathbf{m}_{a_{j-1}}| \sqrt{n} + \|\zeta\|_2). \end{aligned}$$

For $s \geq 1$ and $1 \leq i < 2^j$, by (117),

$$|\chi_i^T Q_j^s v^{a_j}| \leq n^2 |\mathbf{m}_{a_{j-1}}| e^{-\Omega(s/n^2)}. \quad (120)$$

Recall that $j \geq 2$. To prove (116), we distinguish between two cases: whether the birds $\mathcal{B}_i, \mathcal{B}_{i+1}$ are joined at node a_j or earlier.

Case I. ($i = 2^{j-1}$): The edge $(i, i+1)$ is created at node a_j and $h(i) = j$, where $2 \leq j < \log n$ (Figure 33). We begin with the case $t = t_j$. By construction, the upper bound in (116) is equal to 1. To establish the lower bound, we observe that at time $t_j - 1$ the two middle birds were more than one unit of distance apart.

Figure 33: The birds \mathcal{B}_i and \mathcal{B}_{i+1} are joined together at time t_j .

By the expression of the velocity given in (117), which expresses the displacement prior to t_j , neither bird moved by more than $(1 + e^{-n})|\mathbf{m}_{a_{j-1}}|$ in that one step; therefore,

$$\text{DIST}_{t_j}(\mathcal{B}_i, \mathcal{B}_{i+1}) > 1 - 3|\mathbf{m}_{a_{j-1}}|, \quad (121)$$

which exceeds the lower bound of (116), ie, $1 - \frac{5}{3}(n^5 + jn^4)|\mathbf{m}_{a_{h(i)-1}}|$. Assume now that $t_j < t \leq t_{j+1}$. Observe that

$$\mathbf{1}_{2^j} \left(\overbrace{\left(\frac{1}{2}, 1, \dots, 1, \frac{1}{2} \right)}^{2^j} \right) \left\{ \begin{pmatrix} 1 \\ -1 \end{pmatrix} \otimes \mathbf{1}_{2^{j-1}} \right\} = 0.$$

The i -th row of P_j is the same as the $(2^j + 1 - i)$ -th row read backwards. This type of symmetry is closed under multiplication, so it is also true of P_j^s . By (83), for any $s \geq 0$, it then follows that

$$Q_j^s \left\{ \begin{pmatrix} 1 \\ -1 \end{pmatrix} \otimes \mathbf{1}_{2^{j-1}} \right\} = P_j^s \left\{ \begin{pmatrix} 1 \\ -1 \end{pmatrix} \otimes \mathbf{1}_{2^{j-1}} \right\} = \left(b_1^{(s)}, \dots, b_{2^{j-1}}^{(s)}, -b_{2^{j-1}}^{(s)}, \dots, -b_1^{(s)} \right)^T.$$

The following recurrence relation holds: $b_i^{(0)} = 1$ if $1 \leq i \leq 2^{j-1}$, and $b_i^{(0)} = -1$ else. For $s \geq 0$, we get the identities below for $l \leq 2^{j-1}$, plus an antisymmetric

set for $l > 2^{j-1}$:

$$b_l^{(s+1)} = \frac{1}{3} \begin{cases} b_1^{(s)} + 2b_2^{(s)} & \text{if } l = 1; \\ b_{l-1}^{(s)} + b_l^{(s)} + b_{l+1}^{(s)} & \text{if } 1 < l < 2^{j-1}; \\ b_{2^{j-1}-1}^{(s)} & \text{if } l = 2^{j-1}; \\ -b_{2^{j-1}-1}^{(s)} & \text{if } l = 2^{j-1} + 1; \\ -b_{2^j+2-l}^{(s)} - b_{2^{j+1}-l}^{(s)} - b_{2^j-l}^{(s)} & \text{if } 2^{j-1} + 1 < l < 2^j; \\ -b_1^{(s)} - 2b_2^{(s)} & \text{if } l = 2^j. \end{cases}$$

We find by induction that

$$b_1^{(s)} \geq \dots \geq b_{2^{j-1}}^{(s)} \geq 3^{-s};$$

therefore,

$$\chi_{2^{j-1}}^T Q_j^s \left\{ \begin{pmatrix} 1 \\ -1 \end{pmatrix} \otimes \mathbf{1}_{2^{j-1}} \right\} = -2b_{2^{j-1}}^{(s)} < -3^{-s}. \quad (122)$$

Since the two middle birds in the flock F_{a_j} get attached in the flocking network at time t_j , $\text{DIST}_{t_j}(\mathcal{B}_i, \mathcal{B}_{i+1}) \leq 1$. Assume that F_{a_j} does not undergo a flip. Then, by (117, 118, 119), for $t_j < t \leq t_{j+1}$,

$$\begin{aligned} \text{DIST}_t(\mathcal{B}_i, \mathcal{B}_{i+1}) &\leq 1 + \sum_{s=1}^{t-t_j} \chi_i^T Q_j^s v^{a_j} \\ &\leq 1 + |\mathbf{m}_{a_{j-1}}| \sum_{s=1}^{t-t_j} \chi_{2^{j-1}}^T Q_j^s \left\{ \begin{pmatrix} 1 \\ -1 \end{pmatrix} \otimes \mathbf{1}_{2^{j-1}} \right\} + \sum_{s=1}^{t-t_j} \chi_{2^{j-1}}^T Q_j^s \zeta \\ &\leq 1 - \frac{1}{3} |\mathbf{m}_{a_{j-1}}| + \sum_{s \geq 1} |\chi_{2^{j-1}}^T Q_j^s \zeta| \\ &\leq 1 - \frac{1}{3} |\mathbf{m}_{a_{j-1}}| + |\mathbf{m}_{a_{j-1}}| \sum_{s \geq 1} e^{-\frac{1}{2}n - sn^{-3}} \\ &< 1 - \frac{1}{3}(1 - o(1)) |\mathbf{m}_{a_{j-1}}| = 1 - \frac{1}{3}(1 - o(1)) |\mathbf{m}_{a_{h(i)-1}}|, \end{aligned}$$

which proves the upper bound in (116) for $i = 2^{j-1}$. The negative geometric series we obtain from (122) reflects the ‘‘momentum’’ (minus the vibrations) of the two flocks colliding and penetrating into each other’s zone of influence before being stabilized.

Suppose now that the flock F_{a_j} undergoes a flip at time $t_j + n^f$. The previous analysis holds for $t_j < t \leq t_j + n^f$; so assume that $t_j + n^f < t \leq t_{j+1}$. By (120) and $h(i) = j$,

$$\sum_{s=1}^{t-t_j-n^f} |\chi_i^T Q_j^{s+n^f} v^{a_j}| \leq \sum_{s=1}^{t-t_j-n^f} n^2 |\mathbf{m}_{a_{h(i)-1}}| e^{-\Omega(sn^{-2} + n^{f-2})} = o(|\mathbf{m}_{a_{h(i)-1}}|).$$

By (118), therefore,

$$\begin{aligned}
\text{DIST}_t(\mathcal{B}_i, \mathcal{B}_{i+1}) &= \text{DIST}_{t_j}(\mathcal{B}_i, \mathcal{B}_{i+1}) + \sum_{s=1}^{n^f} \chi_i^T Q_j^s v^{a_j} - \sum_{s=n^f+1}^{t-t_j} \chi_i^T Q_j^s v^{a_j} \\
&\leq \text{DIST}_{t_j+n^f}(\mathcal{B}_i, \mathcal{B}_{i+1}) + \sum_{s=1}^{t-t_j-n^f} |\chi_i^T Q_j^{s+n^f} v^{a_j}| \\
&< 1 - \frac{1}{3}(1 - o(1))|\mathbf{m}_{a_{h(i)-1}}| + o(|\mathbf{m}_{a_{h(i)-1}}|) < 1 - \frac{1}{4}|\mathbf{m}_{a_{h(i)-1}}|.
\end{aligned}$$

This establishes the upper bound in (116) for $i = 2^{j-1}$, whether there is a flip or not. We prove the lower bound as follows. By (118, 120, 121), for $t_j < t \leq t_{j+1}$,

$$\begin{aligned}
\text{DIST}_t(\mathcal{B}_i, \mathcal{B}_{i+1}) &\geq 1 - 3|\mathbf{m}_{a_{j-1}}| - \sum_{s=1}^{t-t_j} |\chi_i^T Q_j^s v^{a_j}| \\
&\geq 1 - 3|\mathbf{m}_{a_{j-1}}| - n^2|\mathbf{m}_{a_{j-1}}| \sum_{s \geq 1} e^{-\Omega(s/n^2)} \\
&\geq 1 - n^5|\mathbf{m}_{a_{j-1}}| = 1 - n^5|\mathbf{m}_{a_{h(i)-1}}|.
\end{aligned}$$

Note that this derivation still holds if the flock “flips,” ie, reverses the sign of $Q_j^s v^{a_j}$. This establishes (116) for $i = 2^{j-1}$.

Figure 34: The birds \mathcal{B}_i and \mathcal{B}_{i+1} are joined earlier than t_j .

Case II. ($i < 2^{j-1}$): This implies that $h(i) < j$ (Figure 34). Recall that $j \geq 2$. We omit the case $i > 2^{j-1}$, which is treated similarly. The case $t = t_j$ follows

by induction¹⁵ for $j' = j - 1$ and $t = t_{j'+1}$. Note that $t \neq t_{j-1}$, so the inductive use of (116) does not provide 1 as an upper bound; furthermore it provides even stronger bounds, as $j' < j$. We assume now that $t_j < t \leq t_{j+1}$. By (118, 120),

$$\begin{aligned} |\text{DIST}_t(\mathcal{B}_i, \mathcal{B}_{i+1}) - \text{DIST}_{t_j}(\mathcal{B}_i, \mathcal{B}_{i+1})| &\leq \sum_{s \geq 1} |\chi_i^T Q_j^s v^{a_j}| \\ &\leq n^2 |\mathbf{m}_{a_{j-1}}| \sum_{s \geq 1} e^{-\Omega(s/n^2)} \leq O(n^4 |\mathbf{m}_{a_{j-1}}|). \end{aligned}$$

We apply (116) inductively once more for $j' = j - 1$ and $t = t_{j'+1}$:

$$1 - \frac{5}{3}(n^5 + (j-1)n^4) |\mathbf{m}_{a_{h(i)-1}}| \leq \text{DIST}_{t_j}(\mathcal{B}_i, \mathcal{B}_{i+1}) \leq 1 - \frac{1}{4}(1 - \frac{1}{n}(j-1)) |\mathbf{m}_{a_{h(i)-1}}|;$$

hence, for $t_j < t \leq t_{j+1}$,

$$\begin{aligned} 1 - \frac{5}{3}(n^5 + (j-1)n^4) |\mathbf{m}_{a_{h(i)-1}}| - O(n^4 |\mathbf{m}_{a_{j-1}}|) &\leq \text{DIST}_t(\mathcal{B}_i, \mathcal{B}_{i+1}) \leq \\ &1 - \frac{1}{4}(1 - \frac{1}{n}(j-1)) |\mathbf{m}_{a_{h(i)-1}}| + O(n^4 |\mathbf{m}_{a_{j-1}}|). \end{aligned}$$

Because $j > h(i)$, by (89), $|\mathbf{m}_{a_{j-1}}| < n^{-c} |\mathbf{m}_{a_{h(i)-1}}|$, for $h(i) > 1$. In the case $h(i) = 1$,

$$|\mathbf{m}_{a_{j-1}}| \leq |\mathbf{m}_{a_1}| < n^{-c} \leq 4n^{-6} |\mathbf{m}_{a_0}| = n^{-11},$$

for $c \geq 11$. This shows that, in all cases, $|\mathbf{m}_{a_{j-1}}| < 4n^{-6} |\mathbf{m}_{a_{h(i)-1}}|$; hence (116). Since sums involving velocities are immediately taken with absolute values, the same derivation can be repeated verbatim in the case of a flip. \square

5 Concluding Remarks

We have established the first general convergence bound for a standard neighbor-based flocking model. We believe that it can be generalized to many of the metric and topological variants of the Vicsek model. We have shown that the spectral shift underpinning the slow convergence is resistant to noise decaying with time. Without temporal decay, injecting a fixed amount of entropy into the system at each step is likely to produce widely different behaviors. Whether the techniques introduced in this work, in particular the geometric approach, can shed light on phase transitions reported experimentally in [3, 29] is a fascinating open question.

Acknowledgments

I wish to thank Iain Couzin, Joel Friedman, Phil Holmes, Ali Jadbabaie, and Naomi Leonard for helpful discussions.

¹⁵If the reader is wondering why our induction invariant is defined over the interval $[t_j, t_{j+1}]$ and not $(t_j, t_{j+1}]$, the benefit is a shorter presentation.
