With the advent of chip multiprocessors, exploiting intra-transaction parallelism in database systems is an attractive way of improving transaction performance. However, exploiting intra-transaction parallelism is difficult for two reasons: first, significant changes are required to avoid races or conflicts within the DBMS; and second, adding threads to transactions requires a high level of sophistication from transaction programmers. In this article we show how dividing a transaction into speculative threads solves both problems—it minimizes the changes required to the DBMS, and the details of parallelization are hidden from the transaction programmer. Our technique requires a limited number of small, localized changes to a subset of the low-level data structures in the DBMS. Through this method of incrementally parallelizing transactions we can dramatically improve performance: on a simulated 4-processor chip-multiprocessor, we improve the response time by 44–66% for three of the five TPC-C transactions.

Categories and Subject Descriptors: H.2.4 [Database Management]: Systems—Concurrency, Transaction processing; C.1.2 [Computer Systems Organization]: Processor Architectures—Parallel Architectures; D.3.4 [Programming Languages]: Processors—Compilers

General Terms: Design, Experimentation, Performance

Additional Key Words and Phrases: Thread-level speculation, optimistic concurrency, chip-multiprocessing, incremental parallelization

---

Copyright and Reuse: This article extends a previous conference publication [Colohan et al. 2005] in several significant ways, providing valuable additional information for database system programmers and speculative multithreading researchers: (i) we have expanded on how to use TLS as a programming system, and how threads are managed; (ii) we provide a more in-depth background and tutorial of previous and concurrent related work; (iii) we have added a new section examining the intra-transaction dependences and exactly how we divided each TPC-C transaction into speculative threads; (iv) we measure and discuss the progress of incremental optimization for all benchmark transactions (not just new-order).

1. INTRODUCTION

We are in the midst of a revolution in microprocessor design: all of the major computer manufacturers are producing computer systems that feature chip multiprocessors (CMPs) and simultaneous multithreading (SMT). Examples include Intel’s “Smithfield” (dual-core Pentium IV’s with 2-way SMT), IBM’s Power 5 (combinable, dual-core, 2-way SMT processors), AMD’s Opteron (dual-core), and Sun Microsystems’s Niagara (an 8-processor CMP). How can database systems exploit this increasing abundance of hardware-supported threads? Currently, for OLTP workloads, threads are primarily used to increase transaction throughput; ideally, we could also use these parallel resources to decrease transaction latency. Although most commercial database systems do exploit intra-query parallelism within a transaction, this form of parallelism is only useful for long running queries, while OLTP workloads tend to issue multiple short queries. To the best of our knowledge, commercial database systems do not exploit intra-transaction parallelism [IBM Corporation 2004; Miller and Lau 2001; Zuzarte 2005], and for good reason.

Parallelizing a transaction is difficult. First, the DBMS must be modified to support multiple threads per transaction. Latches (a.k.a. mutexes) must be added to data structures which are shared between threads in the transaction. These latches add complexity and hinder performance. Second, the transaction must be divided into parallel threads. Consider the NEW ORDER transaction, the prevalent transaction in TPC-C [Gray 1993] (Figure 1), which simulates the workload of a database server owned by a bank or business selling widgets. We can parallelize the main loop (which represents 78% of the execution time) such that each loop iteration runs as a thread. The transaction programmer must understand when these threads may share data, and add inter-thread locks to avoid problems; e.g., the thread should use inter-thread locks to ensure that only one thread updates the quantity of an item in the stock table at a time. Finally, the transaction programmer must test the new transaction to ensure that the resulting parallel execution is correct and ensure that no new deadlock conditions or subtle race conditions were introduced, and then repeat the entire process until satisfactory performance is achieved.

The difficulty in parallelizing a transaction lies in data dependences between threads. When any two threads may share data, synchronization must be added to preserve program
Incrementally Parallelizing Database Transactions with Thread-Level Speculation

semantics. By adding locks and latches into the source code, the programmer is letting the system know what invariants must hold to compute the correct result. But the programmer must be conservative, and protect against all possible sharing patterns. The challenge with this conservative programming model is that the programmer must add latches and locks to preserve correctness: if the programmer does not have a deep understanding of the entire program, then they will likely either unknowingly introduce bugs by omitting essential locks, or else degrade performance by adding unnecessary locks. Instead we would prefer a more aggressive programming model that allows the programmer to focus on performance rather than correctness.

1.1 Incremental Parallelization with Thread-Level Speculation

Thread-Level Speculation (TLS) [Gopal et al. 1998; Hammond et al. 2000; Steffan et al. 2000; Tremblay 1999; Zhang et al. 1999] empowers the programmer to speculatively parallelize code while being concerned only with performance rather than correctness. With TLS, the programmer specifies where to break a transaction into threads, or epochs 2 and the TLS mechanism executes them in parallel while preserving the original sequential semantics of the program. The TLS mechanism preserves sequential semantics by tracking data dependences between epochs and restarting epochs when their execution diverges from the original sequential execution.

Figure 2 illustrates the basic operation of TLS, where sequential code (Figure 2(a)) is divided into epochs which are executed in parallel by the system (Figure 2(b)). The system is aware of the original sequential order of the epochs, and also observes every read and write to memory that the epoch performs (i.e. the reads and writes through p and q). The system observes whether epoch 1 ever writes to a memory location which has already been read by epoch 2—if so, then epoch 2 has violated sequential semantics, and is rewound and re-executed with the correct value.

This article describes our experience in incrementally parallelizing database transactions

---

2We refer to the parallel threads in TLS as epochs to differentiate them from the explicit threads which may also exist in the system. For example, in a database system each transaction runs on a thread, and we break each of those transaction threads up into epochs.
using TLS—in particular, how small changes can be made to the DBMS to avoid the most problematic data dependences between epochs. The result is a significant latency improvement for database transactions—on a simulated 4-processor chip-multiprocessor, the response time is improved by 46–66% for three of the five TPC-C transactions. To achieve these impressive performance benefits we need to modify both the transaction code and the code in the DBMS.

Transaction programmers are primarily concerned with creating functional applications. We do not want to teach transaction programmers new sophisticated programming techniques, nor do we want to introduce new failure modes into their applications. We let the transaction programmer treat TLS as a switch. This switch can be enabled or disabled for any loop in the transaction, and the only effect visible to the transaction programmer is that TLS may provide improved performance when TLS is enabled (Figure 3(a)). TLS can extract parallelism from within a transaction without changing the original sequen-
tional execution semantics, meaning that TLS will not introduce any new bugs (although the change in performance may uncover hidden race conditions which already existed in the original code). The interface to TLS used by the transaction programmer can be as simple as providing performance hints without having to modify the transaction software.

Database vendors want to provide high performance database systems to customers. At the same time, existing database systems are very large and complex systems, and so the database system programmers are reluctant to make changes which modify large portions of the database system. To apply TLS, the database system programmer engages in an iterative process (Figure 3(b)): starting with a sequential transaction, the DBMS programmer marks some loops for TLS execution, and then examines the execution profile provided by the hardware. This profile information indicates which loads and stores in the transaction caused dependence violations that in turn reduced performance. The DBMS programmer then optimizes just this performance critical code, and repeats the process. We show that this tuning process requires modifying only a small fraction of the DBMS code (we only modified 1200 out of 180,000 lines of code in BerkeleyDB), and yet eliminates the majority of the data dependences which cause violations. Hence the gains of TLS can be obtained through a small effort on the part of the database vendor.

1.2 Why Transaction Latency?
You may believe that transaction throughput is all that matters for database systems, and in particular for OLTP workloads. Why are we attacking transaction latency? First, there is the obvious reason to improve latency: improving latency makes users happy by improving system response time. The second reason is more subtle: on modern systems, OLTP workloads such as TPC-C are frequently lock-bound [McWherter et al. 2004]. If the system is lock-bound, then to improve performance we need to decrease the time spent waiting for locks. TLS can be used to improve the latency of a transaction that holds contended locks and hence the transaction will release those locks more quickly, resulting in an improvement in overall transaction throughput [McWherter et al. 2005].

1.3 Related Work
The previous and concurrent work which inspired and influenced our research can be divided into three areas: research in intra-transaction parallelism, research in TLS software support, and research in TLS hardware support. We now discuss each of these in greater detail.

1.3.1 Intra-transaction Parallelism. Traditionally, high-performance database systems have targeted inter-transaction parallelism, or intra-operation parallelism, while this article introduces new techniques for exploiting intra-transaction parallelism. Previous work on intra-transaction parallelism has focused on techniques which do not require modifying the DBMS: With Sagas the programmer is able to define a long-running transaction, known as a saga, which is composed of several DBMS-visible transactions. By using sagas a long transaction could execute without holding locks for an extended period of time. To allow a sagas to abort the transaction programmer would have to create compensating transactions which undo the side-effects of the individual transactions within the saga. TLS is complimentary to sagas—TLS can be used instead of sagas to allow a long running transaction to complete faster (and release its locks faster); TLS can also be used in addition to sagas to improve the response time of the individual transactions within a saga. TLS is easier to use
since the hardware automates the restarting of epochs, meaning that when using TLS there is no need for the transaction programmer to write *compensating epochs* to allow epochs to abort.

The work on sagas evolved into work on TP-Monitors [Kaufmann and Schek 1996; Rys et al. 1996], which coordinate the execution of the transactions within a saga and allow some of those transactions to execute in parallel, improving performance further. This resulted in work by Shasha *et. al.*, who developed a theoretical basis for automatically breaking a saga into transactions. Shasha showed that if a conflict graph can be constructed for a set of transactions, then the transactions can be *chopped* into smaller transactions which increases the degree of concurrency in the workload [Shasha et al. 1995]. The conflict graph is a static analysis, which allows the transactions within a saga to execute in parallel in the absence of any possible dependences between them. In contrast, TLS is more optimistic: TLS allows epochs to execute in parallel, and only restarts epochs when dependences actually occur. As a result, TLS is able to exploit more parallelism, since it takes advantage of dependence information which is only available at runtime.

### 1.3.2 TLS Software Support

Most previous TLS research has endeavored to have the compiler automatically parallelize programs [Ooi et al. 2001; Bhowmik and Franklin 2002; Vijaykumar 1998; Johnson et al. 2004]. This compiler work grew out of the pioneering work of Knight and Halstead who developed functional languages with support for TLS-style execution [Knight 1986; Halstead 1985]. In this work our goal is to parallelize database transactions. Database transactions and the DBMSs they utilize are not written in functional languages, and it is not practical to re-implement them in functional languages. Compiler based techniques tend to assume perfect knowledge about the whole program to be parallelized, while with databases the transaction is usually compiled separately from the DBMS, and the interface between the transaction and DBMS is kept deliberately simple for portability reasons. We found that transactions naturally decompose into threads which are much larger and more complex than the threads generated by compiler based techniques.

In this article we use hardware-assisted speculative execution to simplify manual parallelization. Prabhu and Olukotun showed that using TLS to assist in manual parallelization has great promise, since it works well when applied to SPEC benchmarks on the Hydra multiprocessor [Prabhu and Olukotun 2003; Hammond et al. 2000]. These results encouraged us to apply TLS to the much larger epochs from the outer loops of database transactions.

Hammond *et. al.* push the idea of programming with epochs to its logical extreme, making the program consist of nothing but epochs; this results in a simpler architecture [Hammond et al. 2004], but requires the programmer to always use epochs [Hammond et al. 2004]. We believe that it is not practical to apply this approach to existing database systems. As a result the work in this article does not enforce a single programming model: programmers can use TLS and epochs when they are desirable, and use either traditional sequential execution or threaded execution as well.

### 1.3.3 TLS Hardware Support

The basic idea behind TLS is inspired by Kung and Robinson’s optimistic concurrency control (OCC) work [Kung and Robinson 1981]. In Kung and Robinson’s paper they propose a mode of execution similar to TLS’s epochs—transactions execute without using locks, and before committing a check for conflicts is
performed, and the transaction rewinds if a conflict is detected. OCC was implemented in software, and achieved reasonable performance by considering only dependences caused by accesses to the database itself. TLS tracks dependences caused by accesses to both the database and the meta-data used to maintain the database. This has two benefits: first TLS is able to extract parallelism from within a single transaction (instead of increasing parallelism between transactions). This means that when speculation fails less work is undone, since only a fragment of the transaction’s execution is rewound. Second, this article shows that the changes to the DBMS software required for achieving good performance with TLS are localized, while applying OCC requires changing the fundamental locking methodology used by the entire DBMS.

The optimistic concurrency control work inspired a hardware implementation called transactional memory [Herlihy and Moss 1993], which showed how the processor caches can be used to buffer speculative state. The transactional memory work led to a tech report which did a preliminary investigation of TLS-style execution [Morrisett and Herlihy 1993]. The hardware design in this article builds on this idea, using the caches to buffer speculative state.

The first major study of how to implement a complete TLS system in hardware was the Multiscalar project from Wisconsin [Franklin and Sohi 1996; Sohi et al. 1995]. The initial Multiscalar featured an architecture optimized purely for TLS-style execution. Programs were broken up into tasks (equivalent to TLS epochs), and each task was run on a separate CPU. Register dependences were handled through a fast register forwarding ring, and memory dependences were resolved through a centralized address resolution buffer [Franklin and Sohi 1996]. Later this design was refined to use the caches to detect and buffer memory dependences, in the form of the speculative versioning cache [Gopal et al. 1998]. The success of the Multiscalar project inspired numerous other TLS research projects, including the IACOMA project [Prvulovic et al. 2001], the Hydra project [Hammond et al. 2000], and our Stampede project [Steffan and Mowry 1998; Steffan et al. 1997; Steffan et al. 2000; 2002; Zhai et al. 2002; 2004]. This research also inspired work on a few software-only TLS designs [Gupta and Nim 1998; Rauchwerger and Padua 1999; Rundberg and Stenstrom 2000] and hardware-only TLS designs [Akkary and Driscoll 1998; Marcuello and González 1999; Rotenberg et al. 1997]. An interesting comparison of many of these schemes was done by Garzarán et al. [Garzarán et al. 2003].

One of the ways which we avoid dependences in this article is to delay lock and latch operations during the execution of an epoch, and optimistically assume there will not be conflicts before the epoch commits. There are two differences between this technique and optimistic concurrency control [Kung and Robinson 1981; Herlihy and Moss 1993]: (i) epochs are much smaller than transactions (in our experiments we have between 2 and 192 epochs per transaction), and (ii) transactions using speculation in our TLS scheme are able to correctly interact with non-speculative transactions with no changes to the non-speculative transactions.

This article adds an important capability to prior hardware designs: we use sub-epochs [Colohan et al. 2006] to tolerate data dependences between speculative epochs. Sub-epochs (a.k.a. sub-threads) are a form of checkpointing, and in this article sub-epochs are used to reduce the penalty due to failed speculation. Using checkpoints in epochs was previously proposed by Olukotun et al. [Olukotun et al. 1999]—in their work they found that checkpoints had little benefit, since they were considering workloads with small epochs.
The large epochs found in our database workloads improve dramatically with the use of sub-epochs (checkpoints).

1.4 Contributions
This article makes the following contributions: (i) it solves the problem of parallelizing the central loop of a transaction, which reduces transaction latency and hence decreases contention for resources used by the transaction; (ii) it provides a methodology for eliminating the data dependences which limit parallel performance, describing three specific techniques for eliminating these dependences and examples of their application; (iii) it demonstrates the application of these techniques by incrementally parallelizing transactions running on a real DBMS, and by describing this process in detail for several TPC-C transactions.

2. APPLYING TLS TO DATABASE TRANSACTIONS
In this section we provide an overview of the process of using TLS to incrementally parallelize a database transaction. We begin by discussing the issues involved in dividing a transaction into epochs. We then present the details of managing epochs and the underlying speculative threads. Finally, we introduce several techniques and tools for tolerating data dependence violations between epochs, and optimizing the performance of large epochs.

2.1 Dividing a transaction into epochs
Consider the for-loop in Figure 4, which is a highly simplified version of the central loop of the NEW ORDER transaction from TPC-C. This loop simply finds items in a database
table and decrements their quantity field. Let’s assume that the programmer knows that the elements in the items array are disjoint—this means that if the programmer looked at just the loop, they would presume that the loop is parallel, and each loop iteration could be run as a parallel epoch. If a transaction programmer were trying to apply TLS, then this loop would be a good candidate for parallelization.

But what about the select and update functions? If we look at the definitions of those functions (also in Figure 4), we observe that they increment the variables num_selects and num_updates. The increments will cause data dependences between our epochs, shown in Figure 5(a). Furthermore, the select and update functions call btree_lookup, and we do not know what dependences may exist in the B-tree code.

The data dependences between epochs must be preserved for correct execution. To preserve dependences any load in epoch 2 must load the correct value from the last store.

Fig. 5. TLS execution of the example loop.
to that memory location by epoch 1 or any earlier epoch. In Figure 5(a) we show several backwards dependences, where the load executes before the last store in the previous epoch executes. When TLS detects a backwards dependence it is known as a dependence violation, and it restarts the epoch (Figure 5(b))\(^3\). In addition to restarting the epoch, all later epochs are restarted as well through a chain violation since they may have consumed incorrect speculative values from the violated epoch. When the violated epoch re-executes, the backwards dependence that triggered the violation is turned into a forwards dependence, and hence the correct result is computed.

Dependence violations cause work to be discarded and re-executed, and hence they limit performance. The following techniques have been proposed in previous work to mitigate the performance impact of violated data dependences.

Limit epoch sizes. Restarting large epochs throws away a large amount of work, which is not efficient. Using small epochs limits the amount of wasted work when a violation occurs.

Choose epochs to avoid dependences. Dependences can be avoided by carefully choosing when to apply TLS at all, and by carefully choosing epoch boundaries [Vijaykumar 1998].

Choose epochs to avoid backwards dependences. Sometimes dependences can not be avoided completely—in these cases it makes sense to either choose epochs to try and avoid backwards dependences, or to apply compiler scheduling techniques to the epochs in an attempt to turn backwards dependences into forwards dependences [Vijaykumar 1998; Zhai et al. 2004].

Use compiler managed synchronization. If a dependence occurs frequently, insert explicit synchronization between the last store in an epoch and the first load of the next epoch to avoid a violation [Zhai et al. 2004].

Use hardware managed synchronization. If hardware detects a load-store pair which causes frequent violations, insert synchronization which ensures that the load does not issue until the store retires [Steffan et al. 2002].

Use value prediction. Detect which loads frequently cause violations, and use a value predictor to predict the correct value consumed by the load [Oplinger et al. 1999].

To parallelize database transactions while minimizing transaction programmer effort, we started with a simple division into epochs: we made each loop iteration in the transaction into an epoch. The resulting epochs had the following properties:

—The epochs were large. Previous work has studied epochs with various size ranges, including 3.9–957.8 dynamic instructions [Vijaykumar 1998], 140–7735 dynamic instructions [Prabhu and Olukotun 2003], 30.8–2,252.7 dynamic instructions [Steffan et al. 2002], and up to 3,900–103,300 dynamic instructions [Garzarán et al. 2003]. The epochs studied in this article are quite large, with 7,574–489,877 dynamic instructions.

—There were many violation-causing dependences between epochs. This makes intuitive sense given the significantly increased sizes of the epochs.

\(^3\)In this discussion we assume that only backwards dependences can cause violations, because the TLS hardware [Colohan et al. 2006] makes an epoch’s stores (updates) available to later epochs as soon as possible. Using such a design with aggressive update propagation ensures that the number of violations is minimized, which is important when the epochs are large (and hence the penalty of a violation is large).
—The epochs were not amenable to compiler based synchronization techniques. The majority of dependences were on shared state managed by the DBMS code, and not the transaction code. The DBMS code is shared by many transactions, and synchronization inserted for the benefit of one transaction was not useful for the execution of other transactions.

—The execution challenged hardware-based prediction and synchronization techniques: a given epoch in our database transactions has tens to hundreds of potential data dependences which have to be correctly predicted, while any mis-prediction results in the entire epoch being rewound. Our most accurate hardware-based predictors were unable to predict and synchronize our transactions effectively.

To overcome these challenges we adopted the following two-pronged approach.

1. We incrementally modified the DBMS to avoid or remove data dependences which frequently trigger violations. In this section we examine how removing or avoiding dependences affects performance; in Section 4 we apply these techniques to the DBMS to remove dependences.

2. We extended hardware support to divide each epoch into sub-epochs, so that a single violation does not cause the entire epoch to be rewound. We give a brief overview of the operation of sub-epochs in this section; more detail is available in previous publications [Colohan 2005; Colohan et al. 2006].

2.2 Life Cycle of an Epoch
To parallelize the loop from Figure 4, we need to break the loop up into epochs. The code which does this is shown in Figure 6. Note that the loop body is untouched, and we have just inserted template code to exploit TLS functionality. In particular, the inserted template code in Figure 6 does the following:

① A new function, `tfork`, is used to create a thread to run each loop iteration as an epoch. Note that the loop is structured so that `tfork` can fail if there are no CPUs (or epoch contexts on a CPU) available to run another thread—this allows TLS to dynamically adapt to the number of available CPUs.

② Each thread receives arguments using a designated portion of the stack known as the forwarding frame [Steffan et al. 2005].

③ The boundaries of speculative execution are marked with the `become_speculative` and `become_nonspeculative` functions.

④ Template code ensures that the epochs commit their speculative changes in the original sequential program order by passing a `homefree token`—which indicates that the epoch can no longer be violated by prior epochs—from one thread to the next. When a thread possesses the homefree token it is said to be `homefree` and can no longer be violated by an older epoch.

The execution of our sample loop with these primitives added is illustrated in Figure 7(a).
/* Structure for passing arguments to epochs: */
struct {
    int i;
} forward;
forwarding_frame(&forward);
forwarding_size(sizeof(forward));

for(i=1; i<=num_items; i++) {
    ThreadDescriptor td = tfork();
    if(td != 0) {
        int i = forward.i;
        become_speculative();
        row = stock_table.select(items[i]);
        row.quantity--;
        stock_table.update(items[i], row);
        wait_for_homefree_token();
        become_nonspeculative();
        commit_speculative_writes();
        if(td != TFORK_FAILED) {
            pass_homefree_token(td);
            end_thread();
        }
    }
}
traversal or moving a database cursor. The loop index computation frequently causes a data dependence between epochs, but the index computation is usually not dependent on the body of the loop. If the loop index computation has no side effects then it can be moved up above the speculative region of the loop to the pre-fork region where the loop index is computed before starting the following epoch (❶ in Figure 7(b)). The tfork call effectively acts like a synchronization primitive between epochs, ensuring that the loop index...
computation for an epoch completes before the next epoch begins. This avoids violations due to the loop index. If the tfork primitive supports argument passing between threads (in this article we assume it does) then the loop index value becomes an argument to the next epoch.

Any code placed in the post-homefree region (the portion of an epoch’s execution after the homefree token has arrived but before the token is passed on to the next epoch) (❸ in Figure 7(b)) will not be violated by an earlier thread, since waiting for the homefree token ensures that earlier threads will have committed all of their speculative writes. If some code frequently causes violations, and if that code’s execution can be delayed without affecting correctness, then delaying it until the homefree token has arrived (the post-homefree region) will avoid violations. An example of this is the generation of log sequence numbers in a database system: an epoch in a transaction only generates log sequence numbers, and never consumes them. Because no code in the epoch depends on the generated numbers, it is safe to delay their generation until the post-homefree region.

If too much code is relocated to the post-homefree region then the homefree token may become a bottleneck, serializing execution. To avoid this one can move code further down, after speculation has committed and the homefree token has been passed to the next epoch. This region of execution is known as the post-commit region (❹ in Figure 7(b)). To delay execution until after the homefree token has been passed the code must be thread safe, since it will be executed non-speculatively in parallel with other threads. An example of code which can be delayed until the post-commit region is any call to free. When a transaction frees memory its execution will be unchanged if the free is delayed until after the epoch commits.

In Section 3 we will show numerous examples of how moving code out of the speculative region and into the pre-fork region, post-homefree region and post-commit region can avoid violations when parallelizing the DBMS.

2.4 Avoiding Dependences by Escaping Speculation

Dependences between epochs can often be easier to understand if you look at the higher-level operations being performed, instead of focusing on the individual loads and stores which cause the dependence. For example, consider two epochs which invoke malloc and free, as shown in Figure 8(a). Both the malloc and free routines read and modify shared data structures, namely the free list maintained by the memory allocator. Because of this, any invocations of malloc or free which occur out of the original sequential program order will cause violations.

Since we know that the system allocator is thread safe, it is safe to invoke in the post-commit region. We observe that delaying the freeing of some memory will not affect the correct execution of the program. Therefore it is safe to avoid any dependences caused by free by moving the call to free down to the post-commit region (Figure 8(b)).

It is not possible to move the call to malloc downwards, since the epoch can not proceed until the requested memory is allocated. Instead, we avoid the dependence by escaping the speculation mechanism. Fundamentally, to escape speculation we non-speculatively allocate the memory when requested, and recover by freeing the memory again if speculation fails. To escape the speculation mechanism, we wrap the malloc function with a routine which temporarily disables the speculation mechanism while executing malloc. This wrapper must also carefully check the arguments to malloc (to avoid ridiculously large or frequent memory allocations, which could cause memory exhaustion), and register
a handler which will call free on the allocated memory if the epoch is later violated.

The code wrapper shown in Figure 9 implements this modified version of malloc. In particular, this code does the following:

① Provides thorough argument checking. Since this routine is called from a speculative thread, the parameters could be invalid.

② Acquires a mutex which provides mutual exclusion between epochs within a transaction, to guard against the possibility that malloc was not implemented with intra-transaction concurrency in mind. Note that most implementations of malloc are indeed thread safe, so this extra paranoia can be eliminated once the programmer confirms this.
void *malloc_wrapper(size_t size) {
    static intra_transaction_mutex mut;
    void *ret;

    suspend_speculation();
    check_malloc_arguments(id);
    acquire_mutex(&mut);

    ret = malloc(size);

    release_mutex(&mut);
    on_violation_call(free, ret);
    resume_speculation();

    return ret;
}

Fig. 9. Wrapper for the malloc function which escapes speculation to avoid dependences.

③ Temporarily escapes speculation. While speculation is escaped, the epoch is non-speculative and hence all reads will observe committed machine state and all writes will be immediately visible to the rest of the system (i.e., no buffering occurs). Since no speculative reads are performed, the reads performed by malloc will not cause violations.

④ Saves a pointer to the recovery function, free. If the epoch is violated then free will be called to undo the memory allocation. This is similar to nested top actions in ARIES [Mohan et al. 1992], since we modify the execution but preserve higher level semantics.

Escaping speculation simplifies coding: instead of redesigning the memory allocator to be amenable to TLS execution, we place this simple wrapper around the allocation function. However, this method requires that the malloc function be an isolated undoable operation. The malloc function is undoable: calling free undoes the call to malloc. The malloc function is also isolated: when it is undone via free no other transaction or earlier epoch is forced to rewind or otherwise alter its execution. We can apply the technique of escaping speculation to any operation which satisfies the isolated and undoable properties—in Section 4 we will see further examples of escaping speculation in use.

2.5 Sub-epochs

Data dependences between epochs cause failed speculation, which limits performance. If the transaction was executing on a dataflow architecture [Arvind and Culler 1986] then modifying or re-arranging the code to remove data dependences would directly lead to a performance improvement. Unfortunately, under TLS-style execution performance is limited not only by dependences, but also by where in the epoch they are located. A dependence located early in an epoch causes only a small amount of execution to be rewound, while a dependence located late in an epoch causes most of the epoch to be rewound. In Figure 10 we see that if a programmer eliminates a dependence early in the epoch’s execution then it may hurt performance by exposing a dependence which occurs later in the epoch’s execution.

ACM Journal Name, Vol. TBD, No. TBD, TBD 20TBD.
Performance is hurt because on a violation the TLS mechanism rewinds both the mis-speculated execution which depends on the errant load and all of the correct execution.
which precedes the errant load. When a dependence occurs late in the epoch’s execution then more correct execution is rewound. We can limit the amount of correct execution rewound by using sub-epochs. A sub-epoch can be viewed as a checkpoint of an epoch. Each epoch is divided into multiple sub-epochs. When a violation is detected, it detects which sub-epoch contained the dependent load, and only that sub-epoch (and later sub-epochs) is restarted. Further detail on sub-epochs is available in a previous publication [Colohan et al. 2006], although we provide a brief summary here.

Figure 11 shows the effect of dividing each epoch into two sub-epochs. Since the errant load occurs shortly after the second sub-epoch starts, very little correct execution is rewound when the violation is detected. If you compare Figures 10(a) and 11(b) you see that when using sub-epochs, eliminating the first dependence in Figure 10(a) improves performance.

If using sub-epochs had no cost, then the best performance would be obtained by starting a new sub-epoch before every load instruction—this would completely avoid rewinding correct execution when a violation occurs. We have demonstrated that each sub-epoch consumes finite hardware resources [Colohan et al. 2006]: each additional sub-epoch adds state to each cache line and adds complexity to dependence tracking logic. To conserve these resources we adopt a scheme where new sub-epochs are started periodically during the execution of an epoch (every \( n \) instructions issued), so that the maximum number of correct instructions discarded due to a violation is less than \( n \).

### 2.6 Inter-transaction Data Dependences

Up until this point we have discussed the TLS execution of a single transaction. A transaction runs on a thread\(^5\), which may be further subdivided into epochs. How do the speculative epochs within a transaction’s thread interact with other threads in the DBMS?

As a thread executes it performs loads and stores to memory, and acquires and releases mutexes and locks. All other threads in the system interact with the thread by observing the results of these memory and synchronization operations. To the other threads in the system, a thread which has been divided into epochs with TLS looks like any other thread, but with bursty store behavior—an executing epoch performs no externally visible stores, and all of the epoch’s stores become visible when the epoch commits. You might imagine that performing the stores in a batch instead of in their original program order could introduce concurrency bugs, but modern parallel software already has to tolerate store reordering in hardware, and uses explicit synchronization for communication, based on release consistency [Gharachorloo et al. 1990].\(^6\)

When an epoch executes, it speculatively executes all loads assuming that the loaded values will not change in memory before the epoch commits. If a loaded value is changed before the epoch commits then it triggers a violation, which restarts the epoch from the start of the appropriate sub-epoch. The loaded value can be changed by three sources: (i) by a store performed by an earlier epoch in the same thread; (ii) by a store performed by any non-speculative thread; or (iii) by an epoch from another thread committing. This

\(^5\)In this article a thread refers to the unit of parallelism used by software without TLS. A database system typically maintains a pool of threads, and each thread runs a transaction. TLS adds parallelism by further dividing each thread into epochs.

\(^6\)Section 3 contains further details on how synchronization primitives such as mutexes and locks are correctly handled in TLS execution.
means that stores from the other threads in the system can cause an epoch to be violated.

Does this mean that epochs will be constantly violated by the other threads (running other transactions) in the system? Not at all. A violation is caused by a data dependence between the other thread and the epoch. In Section 4 we show software transformations which eliminate data dependences between epochs in a single thread. These software transformations also serve to eliminate data dependences between threads.

2.7 Summary

We have demonstrated how TLS lets programmers introduce parallelism into a transaction without having to fully understand what data dependences exist in the DBMS’s code. We showed that once a transaction has been speculatively parallelized, data dependences between epochs can be tolerated through code motion, escaping speculation, and sub-epochs. Finally, we demonstrated how a transaction’s use of TLS does not impact the correctness of other transactions, although data dependences between other transactions and a transaction using TLS may incur additional violations. In the two sections that follow we show how TPC-C transactions can be divided into epochs by a transaction programmer, and how the DBMS programmer can tune the DBMS to improve the resulting performance of the speculatively-parallel transactions.

3. THE TRANSACTION PROGRAMMER: DIVIDING TRANSACTIONS INTO EPOCHS

To apply TLS to database transactions, the transaction programmer (or compiler) must first divide the transaction code into epochs. We applied TLS to the transactions from the TPC-C benchmark [Gray 1993], which represent an important class of commercial workloads. Since the TPC-C benchmark specification [Transaction Processing Performance Council 2005] describes the transactions in English, the first thing we required was an implementation. We implemented the five transactions from TPC-C (NEW ORDER, DELIVERY, STOCK LEVEL, PAYMENT and ORDER STATUS) on top of the BerkeleyDB storage manager [Olson et al. 1999]. The implementation is a straightforward and reasonably efficient implementation of the transactions as specified, and does not contain extensive performance optimizations.

The transaction programmer has limited knowledge of the internals of the DBMS, and chooses epochs to minimize data dependences which are apparent in the transaction code they are writing. In Section 4 we will show how to eliminate the most frequent dependences within the DBMS, so that the dependences in the transaction code are all that the transaction programmer has to consider. For the transactions in this article the transaction programmer interacts with the DBMS through the following four basic operations on tables.

Select. The select operation locates the specified row in the table and reads it.

Update. The update operation locates the specified row in the table and modifies it.

Insert. The insert operation adds a new row to the table.

Cursors. A cursor is used to scan through a number of items in the table.

From the transaction programmer’s perspective dependences between epochs are caused by reads and writes performed by the transaction, and by the database operations performed by the transaction. Database operations can form dependences in two ways: (i) a read-after-write (RAW) dependence occurs when an epoch performs an update operation (or updates
a row through a cursor), and a later epoch performs a select operation (or reads a row through a cursor). (ii) an insert dependence occurs when a later epoch performs a select operation (or reads a row through a cursor) then an earlier epoch inserts a new row which changes the result of the later epoch’s select operation.

The TLS mechanism can detect when a RAW or insert dependence on the database data violates the original sequential order, and will restart the epoch or sub-epoch as appropriate. To the TLS mechanism database operations look just like any other memory operations. This is because the database data is mapped into memory whenever it is used. As a result, the TLS mechanism is able to detect violations caused by database operations using the same mechanism which lets it detect violations caused by memory operations.

In the following sections we look at each transaction from TPC-C in detail, examining the dependences which occur due to reads and writes to local variables and due to database operations.

3.1 NEW ORDER

In Figure 12(a) we show a simplified version of the main loop from NEW ORDER. The NEW ORDER transaction is the main transaction from the TPC-C workload, representing at least 45% of executed transactions. NEW ORDER executes on behalf of a customer placing an order for a list of 5–15 items from a warehouse.

We have chosen to make each loop iteration into an epoch. Since the loop covers 78% of the transaction’s execution time, parallelizing it should result in a substantial performance benefit. Examining the code in Figure 12(a), it appears that the only dependence between epochs is due to reads and writes to the stock table. The benchmark specifies that the items to be purchased will be chosen randomly from a uniform distribution of 100,000 items. This means that subsequent epochs are very unlikely to access the same item and cause a data dependence violation.

In Figure 12(b) we show the expected TLS execution: first, the code before the loop begins is executed. Then the loop is run in parallel, and the only violations are caused by infrequent data dependences in the stock table. Recall that when a violation occurs a chain violation causes all later epochs to restart since they may have consumed invalid results from the violated epoch. Since violations are infrequent, we expect this loop to perform quite well—in Section 5 we will see that this is true.

3.2 DELIVERY

The DELIVERY transaction (Figure 13(a)) loops through all of the districts in a warehouse and delivers the oldest outstanding order in each district. This transaction presents two possibilities for parallelization—the inner and outer loops. We chose to parallelize both the inner loop and the outer loop separately (we call the outer loop variant DELIVERY OUTER).

The inner loop represents 63% of the transaction’s execution time. We parallelize this loop such that each iteration is an epoch. The only dependence between epochs is caused by the update of the variable ol_total. Although it is possible to use accumulator variable expansion\(^7\) [Mahlke et al. 1992] to transform the transaction to avoid the ol_total dependence violation,

\(^7\) Accumulator variable expansion is used to eliminate a data dependence caused by a variable which accumulates a value, such as a sum in a dot product. In the DELIVERY example each epoch would be given a private copy of the ol_total variable to update, and once the loop was complete all of those private variables would be

// New Order: Customer ordering a list of items from a
// warehouse.

w_row = warehouse_table.select(w_id);
c_row = customer_table.select(w_id, d_id, c_id);

d_row = district_table.select(w_id, d_id);
o_id = d_row.next_o_id;
d_row.next_o_id++;
district_table.update(w_id, d_id, d_row);

o_row.id = c_id;
o_row.carrier = 0;
order_table.insert(w_id, d_id, o_id, o_row);
neworder_table.insert(w_id, d_id, o_id);

for(i=1...num_items) {
    i_row = item_table.select(items[i]);
st_row = stock_table.select(items[i]);
st_row.quantity--;
stock_table.update(items[i], st_row);

ol_row.item = items[i];
ol_row.price = i_row.price;
orderline_table.insert(w_id, d_id, o_id, i, ol_row);
}

(b) Transaction programmer’s expected execution with TLS.

Fig. 12. The NEW ORDER transaction.

dependence, we assume that the transaction programmer has not optimized it away. When executed, the dependence causes a violation at the end of each and every epoch, as shown in Figure 13(b). From this figure one can see that a frequent dependence violation which causes a small amount of execution to be rewound will have a small impact if TLS is using a small number of CPUs. As the number of CPUs grows, the fraction of execution time spent re-executing epochs grows, since the dependence becomes more and more of a

summed to generate the final value.
bottleneck. In Section 5 we shall see that with up to 8 CPUs this is not a critical bottleneck. The outer loop of the DELIVERY transaction has no dependences, as illustrated in Figure 13(c). In fact, it is completely parallel. The TPC-C benchmark specification allows implementors of TPC-C to take advantage of this by running each outer loop iteration as a separate transaction. We try parallelizing the outer loop using TLS instead of using separate transactions to explore what happens if TLS is used with very large epochs—the epochs in this outer loop decomposition contain an average of 490,000 instructions each.

3.3 STOCK LEVEL

The STOCK LEVEL transaction (Figure 14(a)) is a read-only transaction which checks recently ordered items to see if any items in the warehouse have almost run out. This transaction contains one loop which dominates the transaction’s execution, representing 98% of the transaction execution time. We can parallelize the main loop so that each iteration is an epoch.

The main loop of STOCK LEVEL iterates over a table using a cursor— at the start of each epoch the cursor is read, and at the end of each epoch the cursor is incremented. This forms a dependence from the end of each epoch to the start of the next epoch, which completely serializes execution. To avoid this problem we turn the do-while loop into a while loop, as shown in Figure 14(b). This makes the critical path caused by the cursor as short as possible.

The cursor still forms a dependence between the epochs, which causes each epoch to be violated near the start of its execution, as shown in Figure 14(b). We could add explicit synchronization to the loop to avoid this violation, but we do not do so since we wish to demonstrate the performance gains possible with minimal effort by the transaction programmer. The violations caused by the cursor dependence causes the execution of the rest of the epochs to be somewhat skewed in time. This skew ensures that the infrequent dependences on the found_items set and low_stock variable which occur later in the epoch are executed in-order, which prevents them from causing additional violations.

3.4 PAYMENT

The PAYMENT transaction (Figure 15(a)) is a short transaction which records a payment made by a customer. This transaction contains no loops that cover a significant fraction of execution time. Since the last two operations on the DBMS are independent (updating the customer table and inserting into the history table) we run them as two parallel threads, as shown in Figure 15(b). These two threads cover only 30% of the transaction’s execution, which means that they should not offer a large performance gain.

3.5 ORDER STATUS

The ORDER STATUS transaction (Figure 16(a)) looks up the status of each item ordered by a customer. This transaction contains two loops which cover 38% of the transaction’s execution. The majority of the work done in each loop iteration is a cursor lookup and increment, which forms a dependent chain. Both of these loops are dominated by a dependence on the cursor used in them, so even if run in parallel they will execute in a serialized

---

A cursor is a transaction visible pointer to a location in a database table. A cursor is typically used for traversing the table to scan a range of records in the table. Database systems can also use cursors internally for implementing B-tree searches.
// Delivery: deliver the oldest order in each district in
// the warehouse.
for(d_id=1...DIST_PER_WAREHOUSE) {
    cursor = new order_table.new_cursor(w_id, d_id, OLDEST_O_ID);
    no_row = cursor.fetch_next();
    cursor.delete();
    no_id = no_row.id;

    o_row = order_table.select(no_id, w_id, d_id);
    o_row.carrier_id = carrier_id;
    order_table.update(no_id, w_id, d_id, o_row);

    ol_total = 0;
    for(item=1...o_row.ol_cnt) {
        ol_row = orderline_table.select(w_id, d_id, no_id, item);
        ol_row.date = date();
        ol_total += ol_row.amount;
    }

    c_row = customer_table.select(c_id);
    c_row.balance += ol_total;
    order_table.update(c_id, c_row);
}

fashion (shown in Figure 16(b)).

3.6 Summary
We have summarized in detail the dependences that occur within TPC-C transactions due to local variables and database operations, and reasoned about how to go about dividing each transaction into epochs. We conclude that TLS parallelization is promising for three of the five TPC-C transactions. In the next section we discuss how the DBMS programmer can optimize performance by eliminating dependences between epochs.

4. THE DBMS PROGRAMMER: ELIMINATING DEPENDENCES AND PERFORMANCE TUNING THE DBMS
While our transaction-level analysis concludes that TLS parallelization is promising for three of the five TPC-C transactions, the implementation details of query execution algorithms and access methods in the DBMS reveal more potentially performance-limiting data dependences: read/write accesses to locks, latches, the buffer pool, logging, and B-tree indexes will cause data dependences between epochs. To eliminate these data dependences we propose and analyze three techniques:

(1) **Partition data structures.** A memory allocation operation (malloc) typically uses a single pool of memory, hence parallel accesses to this shared pool will conflict. Using a separate pool of memory for each concurrent epoch avoids such conflicts. Many
ol_row = cursor.data();
item_id = ol_row.id;
if(!found_items.contains(item_id)) {
    found_items.insert(item_id);
}

s_row = stock_table.select(w_id, item_id);
if(s_row.quantity < threshold) {
    low_stock++;
} 
}
while(cursor = cursor.next()) {
ol_row = cursor.data();
item_id = ol_row.id;
if(!found_items.contains(item_id)) {
    found_items.insert(item_id);
}

s_row = stock_table.select(w_id, item_id);
if(s_row.quantity < threshold) {
    low_stock++;
}
}

Fig. 14. Continued.

other dependences are also due to multiple epochs sharing a resource in memory—
these dependences can be avoided by partitioning that resource.

(2) **Escape speculation for isolated undoable operations (IUOs).** This mechanism was
introduced in Section 2.4. The TLS mechanism ensures that all attempts to fetch and
pin a page (pin_page) in the buffer pool by one epoch complete before any invo-
cations of pin_page in the next epoch begin, due to conflicts in the data structures
which maintain LRU information. We prefer to allow pin_page operations to com-

Fig. 16. The ORDER STATUS transaction.
Colohan, Ailamaki, Steffan, and Mowry

An epoch can simply call `pin_page` with speculation escaped: if the epoch is violated then the fetched page just remains in the buffer pool, and `unpin_page` can be invoked to release the page. This works because the `pin_page` operation is undoable and isolated.

(3) **Postpone operations until the end of the epoch.** Techniques for postponing operations were introduced in Section 2.3. When a log entry is generated, it is assigned a log sequence number and increments a global variable. This log sequence number counter forms a dependence between these two epochs. Our key insight was that an epoch never uses log sequence numbers—it only generates them. We can generate log entries during the execution of the epoch, and assign all of the sequence numbers at the end of the epoch after all previous epochs have completed, and just before committing the epoch (which makes the new log entries visible to the rest of the system). When an operation has no impact on the execution of the epoch, and instead only affects other transactions then it can be delayed until the end of the epoch.

In the remainder of this section we tour the database system’s major components, and explain how the database system programmer can eliminate or avoid dependences on the common path in order to increase concurrency for TLS parallelization.

### 4.1 Resource Management

A large portion of every DBMS is concerned with the management of resources, including latches, locks, cursors, private and shared memory, and pages in the buffer pool. All of these resources can be acquired and released. Dependences between epochs occur when two epochs try to acquire the same resource, or when the data structures which track unused resources are shared between epochs. In the discussion that follows we examine each of these resources and develop strategies for executing them in parallel.

#### 4.1.1 Latches

The database system uses latches extensively to protect data structures, and as a building block for locks. Latches are required for correct execution when multiple transactions are executing concurrently, and ensure that only one thread is accessing a given shared data structure at any time. Latches are typically held only briefly—in Section 4.1.2 we discuss locks, which offer concurrency control for database entities.

Latches form a dependence between epochs because of how they are implemented: a typical implementation uses a read-test-write cycle on a memory location (which may be implemented as a test-and-set, load-linked/store-conditional, atomic increment, etc.). This read-test-write cycle can cause a data dependence violation between epochs (Figure 17(a)).

The TLS mechanism already ensures that any data protected by the latch is accessed in a serializable order within a transaction, namely the original sequential program order. However, latches do ensure that mutual exclusion is maintained between transactions, and TLS does not perform that function. So we cannot simply discard the latches; we must instead ensure that they preserve mutual exclusion between transactions without causing violations between the epochs within a transaction.

There are two operations performed on a latch: acquire and release. Let us first consider release operations. When a latch is released, the latch and the data it protects become available to other transactions. Since the modifications made by an epoch are buffered until it commits, we must postpone all release operations until after the epoch has fully

---

9 The term *latch* is from the field of databases. A latch is equivalent to a *mutex* in operating systems parlance.
Next we consider acquire operations. During normal execution, when a latch is acquired it prevents other transactions in the system from changing the associated data. A naïve approach to handling a latch acquire under TLS is to perform the acquire non-speculatively.
at the point when it is encountered. This can be implemented by a recursive latch, which
counts the number of acquires and releases, and makes the latch available to other transac-
tions only when the count reaches zero. This aggressive approach, shown in Figure 17(b),
has a major drawback: since latch releases have been delayed until the end of the epoch,
we have increased the overall size of the critical section. In addition, since we have parallel
overlap between multiple critical sections in a single transaction, the latch may be held for
an extended period of time.

To avoid long critical sections, we can also postpone acquires to the post-homefree re-
gion of the epoch as shown in Figure 17(c). This lazy approach has three parts: (i) all latch
acquires are performed at the end of the epoch, (ii) the buffered speculative modifications
are committed, and finally (iii) all latch releases are performed. This method results in
much smaller critical sections, even when acquire and release operations for a given latch
are encountered repeatedly during an epoch. A potential disadvantage of this approach is
that if another transaction changes the protected data, the epoch will violate and restart.10

Both the lazy and aggressive latch schemes have a potential problem: they re-order the
latch release operations relative to the latch acquire operations as specified in the original
program. If multiple latches are acquired by a single epoch, a deadlock may emerge that is
not possible in the sequential execution, as shown in Figure 18. Although such deadlocks
should be rare, there are two strategies to remedy them: avoidance and recovery. Deadlock
can be avoided using two traditional techniques: (i) perform all latch acquires in a single
atomic operation, or (ii) enforce a global latch acquire ordering [Silberschatz et al. 2002],
such as by sorting the acquire queue by latch address. If avoidance is not possible, we can
instead recover from deadlock once detected (perhaps through a time-out) by violating and
restarting one of the deadlocked epochs. Forward progress is guaranteed because there is
always at least one epoch (the oldest) which executes non-speculatively. The key insight
is that restarting an epoch is much cheaper than restarting the entire transaction since there
are many epochs per transaction.

10This is similar to optimistic concurrency control [Kung and Robinson 1981], except that the optimism is at the
granularity of an epoch instead of a transaction. A latch is held optimistically only for the duration of the epoch
(instead of for the entire transaction), and when a conflict occurs only the epoch rewinds (instead of rewinding
the entire transaction).

ACM Journal Name, Vol. TBD, No. TBD, TBD 20TBD.
4.1.2 Locks. Locks are a more sophisticated form of concurrency control than latches. Instead of providing simple mutual exclusion, locks allow multiple threads into a critical section at the same time if the lock types are compatible: multiple readers are allowed into a critical section at a time, while writers have exclusive access. Locks also provide deadlock detection, since multiple locks can be held at once and they are meant to be held for longer periods of time than latches.

We start by parallelizing locks using a lazy locking scheme, similar to the lazy latch scheme in Section 4.1.1. When an acquire operation is encountered in speculative code, we cannot simply delay the entire acquire operation until the post-homefree region of the epoch, since a handle must be returned. Instead, we return an indirect handle, which is a pointer to an empty handle that is filled in at the end of the epoch when the lock acquire is actually performed.

To summarize our scheme so far, at the end of an epoch all of the lock acquires encountered in that epoch are performed, the changes made by the epoch are committed, and then all of the lock releases encountered in the epoch are performed. This scheme will result in correct execution, but holding all of the locks used by an epoch simultaneously can be a performance bottleneck in the database, particularly for the locks used for searching B-trees. We avoid this problem by recognizing that we can treat read-only and read/write locks differently: at the end of the epoch we (i) acquire and release all read-only locks in the order that the acquire and release operations were encountered during the epoch, we then (ii) perform all read/write lock acquires that were encountered during the epoch, (iii) commit the epoch’s changes to memory, and then (iv) perform all read/write lock releases that were encountered during the epoch. Since a B-tree search involves briefly acquiring a large number of read-only locks, this ensures that those locks are held for minimal time; we need not hold the read-only locks during the epoch commit because the system view of an epoch commit is similar to a transaction commit: it either succeeds or fails. By acquiring and releasing the locks we ensure that the epoch commit does not occur in the middle of a non-read-only critical section in some other transaction. If latches were labeled as read-only or read/write then this optimization could also be applied to latches in addition to locks.

4.1.3 Cursor Management. Cursors are data structures used to index into and traverse B-trees. Since they are used quite frequently and their creation is expensive, they are maintained in pre-allocated stacks. Unused cursors are stored in a free cursor stack. A dependence between epochs is created when one epoch puts a cursor onto the free cursor stack and the next epoch removes that cursor from the stack, since both operations manipulate the free pointer. Preserving this dependence is not required for correct execution: the second epoch did not need to get the exact same cursor, but instead wanted to get any cursor from the free stack. We can eliminate this dependence by partitioning the stack, and hence maintaining a separate stack for each processor. This implies that more cursors will have to be allocated, but that each cursor will only be used by the CPU which allocated it, increasing cache locality and eliminating dependences between epochs. An alternative technique would be to escape speculation when allocating cursors, as described in Section 2.4.

---

11Our method of executing lock acquires may also possibly cause a deadlock situation. Similarly to latches, we can recover from a detected deadlock situation by violating and restarting one of the deadlocked epochs.
4.1.4 Memory Allocation. The free cursor pool mentioned above is just a special case of memory allocation. The general purpose memory allocators (such as `malloc`) in the database system introduce dependences between epochs when they update their internal data structures. To avoid these dependences, we must substitute an allocator designed with TLS in mind: in the common case, such an allocator should not communicate between CPUs. Fortunately, this is also a requirement of highly scalable parallel applications. The Hoard memory allocator [E.D. Berger and K.S. McKinley and R.D. Blumofe and P.R. Wilson 2000] is one such allocator, which maintains separate free lists for each CPU, so that most requests for memory do not communicate. An alternative technique would be to escape speculation when allocating memory, as described in Section 2.4.

To avoid dependences caused by `free` operations we delay the execution of `free` operations until the post-commit region of the epoch.

4.1.5 Buffer Pool Management. When either a transaction or the DBMS itself need to read a page of the database, they request that page by invoking the `pin_page` operation on the buffer pool. This operation reads the requested page into memory (if it is not already there), pins it in memory, and returns a pointer to it. Once finished with the page, it is released by the `unpin_page` operation.

Conceptually, the buffer pool is very similar to the memory allocator, since it manages memory. However, the buffer pool is different because users explicitly name the memory they want, and different `pin_page` operations can pin the same page. Therefore, simply partitioning the page pool between epochs will not suffice. Instead, we exploit the fact that the order in which `pin_page` operations take place does not matter. If a speculative epoch fetches the wrong page from disk, we simply must return that page to the free pool. We implement this by executing the `pin_page` function non-speculatively, so that it really does get the page and pin it in a way which is visible to the entire system. If the epoch which called `pin_page` is later violated, we can undo this action by calling `unpin_page`. (This is similar to the compensating transactions used in Sagas [Garcia-Molina and Salem 1987].)

To execute the `pin_page` function non-speculatively we escape speculation, as described in Section 2.4. Relaxing ordering constraints simplifies coding: instead of redesigning the buffer pool to be amenable to TLS execution, we place a simple wrapper around the allocation function. However, this method requires that the `pin_page` function be an isolated undoable operation. The `pin_page` function is undoable: calling `unpin_page` undoes the call to `pin_page`. The `pin_page` is also isolated: when it is undone via `unpin_page` no other transaction or earlier epoch is forced to rewind or otherwise alter its execution.

Similar reasoning shows that the cursor allocation function and `malloc` are also isolated undoable operations, and so this code template could be applied to these functions instead of partitioning their free pools. The `lock_acquire` and `latch_acquire` functions also look like isolated undoable operations—but as we found above in Section 4.1.1, without great care speculatively executing these functions out of original sequential order can cause performance problems (by increasing critical section sizes) or create deadlock.

---

12The buffer pool is the subset of the database pages which currently reside in memory. The buffer pool manager (similar to a virtual memory manager in an operating system) is responsible for retrieving needed pages from disk and writing dirty pages back to disk in response to `pin_page` and `unpin_page` requests.
conditions (by re-ordering lock and latch acquires).

The unpin page operation for the buffer pool is not undoable, since an attempt to undo it with a pin page operation may cause the page to be mapped at a different address. Because of this, we treat it similarly to a lock or latch release operation, and enqueue it to be executed in the post-commit region of the epoch.

4.2 The Log

Every time the database is modified the changes are appended to the log. For recovery to work properly (using ARIES [Mohan et al. 1992]) each log entry must have a log sequence number. Unfortunately, incrementing the log sequence number causes a data dependence between epochs. To avoid this dependence, we modify the logging code to append log entries for speculative epochs to a per-CPU buffer. In the post-homefree region of the epoch we loop over this buffer to assign log sequence numbers to log entries, then append the entire buffer to the log.

4.3 B-Trees

B-trees are used extensively in the database system to index the database. The primary operations involving the B-tree are reading records, updating existing records, and inserting new records. Neither reading nor updating records modify the B-tree, and hence will not cause dependences between epochs. In contrast, insert operations modify the leaf pages of the B-tree. Therefore if the changes made by two epochs happen to fall on the same page then the update of the free space count for that page can cause a violation. If such a violation happens frequently then it may be possible to change the B-tree comparison function so that subsequent inserts do not fall on the same leaf page.

One strength of TLS parallelization is that infrequent data dependences need not be addressed, since the TLS mechanism will ensure correctness in such cases. An example of such an infrequent data dependence is a B-tree page split. Page splits can also cause many data dependences, but since they happen infrequently (by design), we can afford to just ignore them. In the rare cases when page splits occur, the TLS mechanism will ensure their correct sequential execution. The TLS mechanism provides a valuable fallback, allowing the programmer to avoid the effort of designing an algorithm for parallel page splits.

The B-tree code in BerkeleyDB contains a simple performance optimization: when a search is requested, it begins the search by inspecting the page located by the previous search through a “last page referenced” pointer (this assumes some degree of locality in accesses). Accesses to this pointer cause a data dependence between epochs. Since the resulting violations can hurt performance, we decided to disable this “last page” optimization for TLS execution. Alternatively, one could retain this optimization without causing violations by maintaining a separate “last page reference” pointer per CPU.

4.4 Statistics Gathering

The database system gathers statistics on its internal operations by incrementing counters. Every time a counter is incremented in two consecutive epochs a dependence is created. Since these counters are frequently updated and rarely read, they are parallelized by creating a private copy of each counter per CPU. When the counter is read the sum of all of the private values is computed.
4.5 Error Checks
This work indicates that error checking code in the database system can occasionally cause
dependences between epochs. The most important of these is a dependence caused by ref-
ence counting for cursors—a mechanism in the DBMS which tracks how many cursors
are currently in use by a transaction, and ensures that none are in use when the transaction
commits. Since this code is solely for debugging a transaction implementation, it can be
safely removed once the transaction has been thoroughly tested.

4.6 False Sharing
To minimize overhead, the TLS mechanism tracks data dependences at the granularity of
a cache-line. However, accesses to different variables which happen to be allocated on the
same cache line can cause data dependence violations due to false sharing [Torrellas et al.
1990; Eggers and Jeremiassen 1991]. This problem can be remedied by inserting padding
to ensure that variables which are frequently-accessed by different CPUs are not allocated
on the same cache line [Jeremiassen and Eggers 1995].

5. EXPERIMENTAL RESULTS
In this section we evaluate the incremental parallelization of transactions using TLS, and
show the resulting performance gains.

5.1 Benchmark Infrastructure
Our experimental workload is composed of the five transactions from TPC-C (NEW OR-
DER, DELIVERY, STOCK LEVEL, PAYMENT and ORDER STATUS). We have paral-
lelized both the inner and outer loop of the DELIVERY transaction, and denote the outer
loop variant as DELIVERY OUTER. We have also modified the input to the NEW ORDER
transaction to simulate a larger order of between 50 and 150 items (instead of the default
5 to 15 items), and denote that variant as NEW ORDER 150. All transactions are built on
top of BerkeleyDB 4.1.25. Evaluations of techniques to increase concurrency in database
systems typically configure TPC-C to use multiple warehouses, since transactions would
quickly become lock-bound with only one warehouse. In contrast, our technique is able
to extract concurrency from within a single transaction, and so we configure TPC-C with
only a single warehouse. A normal TPC-C run executes a concurrent mix of transactions
and measures throughput: since we are concerned with latency we run the individual
transactions one at a time. TLS improves the performance of CPU bound transactions: if
a transaction spends the majority of its execution time awaiting buffer pool requests then
the transaction is disk bound and not CPU bound. To ensure we are studying CPU bound
transactions, we configure the DBMS with a large (100MB) buffer pool.

---

13 Insertion of padding works for most data structures, but is not appropriate for data structures which mirror
disk-resident data, such as B-tree page headers. In this case, changes will have to be made to the B-tree data
structure itself (see Section 4.3).

14 Our workload was written to match the TPC-C spec as closely as possible, but has not been validated. The
results we report in this article are speedup results from a simulator and not TPM-C results from an actual system.
In addition, we omit the terminal I/O, query planning, and wait-time portions of the benchmark. Because of this,
the performance numbers in this article should not be treated as actual TPM-C results, but instead should be
treated as representative transactions.

15 In a database context, throughput is the rate of transaction execution (transactions executed per minute).

16 This is roughly the size of the entire dataset for a single warehouse.

The parameters for each transaction are chosen according to the TPC-C run rules using the Unix random function, and each experiment uses the same seed for repeatability. The benchmark executes as follows: (i) start the DBMS; (ii) execute 10 transactions to warm up the buffer pool; (iii) start timing; (iv) execute 100 transactions; (v) stop timing.

All code is compiled using gcc 2.95.3 with O3 optimization on a SGI MIPS-based machine. The BerkeleyDB database system is compiled as a shared library, which is linked with the benchmark that contains the transaction code.

To apply TLS to this benchmark we started with the unaltered transaction, marked the main loop within it as parallel, and executed it on a simulated system with TLS support. The system reports back the load and store program counters of the instructions which caused speculation to fail, and we use that information to determine the cause (in the source code) of the most critical performance bottleneck. We then apply the appropriate optimization from Section 4 and repeat.

5.2 Simulation Infrastructure

We perform our evaluation using a detailed, trace-driven simulation of a chip-multiprocessor composed of 4-way issue, out-of-order, superscalar processors similar to the MIPS R14000 [Yea-ger 1996], but modernized to have a 128-entry reorder buffer. Each processor has its own physically private data and instruction caches, connected to a unified second level cache by a crossbar switch. Register renaming, the reorder buffer, branch prediction (GShare [Mc-Farling 1993] with 16KB, 8 history bits), instruction fetching, branching penalties, and
the memory hierarchy (including bandwidth and contention) are all modeled, and are parameterized as shown in Table I. The TLS mechanism is implemented using the hardware design described in a previous publication [Colohan et al. 2006], which includes hardware support for large epochs and 8 sub-epochs per epoch. Latencies due to disk accesses are not modeled, and hence these results are most readily applicable to situations where the database’s working set fits into main memory.

The simulator used to generate these results is a trace driven simulator, which means that the instruction stream of a sequential run is used to drive a parallel timing simulation. Trace driven simulation allows simulation results to be deterministic and allows us to model oracle hardware, but also means that accurately measuring interactions between parallel speculative threads is more challenging. For example, the wrong code paths due to mis-speculation (both due to TLS and due to branch mis-speculations) are simulated by executing the correct path twice, which may slightly underestimate instruction cache misses. Recovery code (such as code executed to undo mis-speculated page get or malloc calls) invoked on a violation is currently not simulated—these functions should take very little time to execute due to the small amount of work they must perform. When a violation is detected while speculation is escaped the epoch restarts immediately, instead of delaying the violation until speculation resumes.

5.3 High Level Benchmark Characterization

We start by characterizing the benchmarks, so we can better understand them. As a starting point for comparison, we run our original sequential benchmark, which shows the execution time with no TLS instructions or any other software transformations running on one CPU of the machine (which is configured with 4 CPUs, cache line replication, and sub-epoch support enabled). This SEQUENTIAL experiment takes between 17 and 509 million cycles (Table II) to execute, but this time is normalized to 100 in Figure 19. (Note that the large percentage of Idle is caused by three of the four CPUs idling in a sequential execution.) When we transform the software to support TLS we introduce some software overheads which are due to new instructions used to manage epochs, and also due to the changes to the DBMS we made to parallelize it. The TLS-SEQ experiment in Figure 19 shows the performance of this parallelized executable running on a single CPU—the additional software overhead is reasonable, varying from -5% to 11% (negative overheads are due to our added code inadvertently improving the performance of the compiler optimizer).

When we apply TLS with our BASELINE hardware configuration with 4 CPUs, 8 sub-
epochs per epoch, 5000 speculative instructions per sub-epoch) we see a significant performance improvement for three of the five transactions, with a 46%–66% reduction in execution time. The PAYMENT and ORDER STATUS transactions do not benefit from TLS: as we saw in Section 3 the PAYMENT contains no loops worth parallelizing, and the threads we chose were limited by a dependence in the locking code which did not affect the other transactions; the main loop in ORDER STATUS contains an unavoidable dependence on a cursor operation.
Is it possible to do better? In the NO SPECULATION experiment we show the performance if the same program is run purely in parallel, incorrectly treating all speculative memory accesses as non-speculative (and hence ignoring all data dependences between epochs)—this is an upper bound on performance, since it shows what would happen if speculation never failed and if no cache space was devoted to the storage of speculative state. This execution does not show linear speedup due to the non-parallelized portions of execution (Amdahl’s law), and due to a loss of locality and communication costs due to spreading of execution over four caches. We find that for NEW ORDER, NEW ORDER 150 and DELIVERY OUTER we are very close to this ideal, and further optimization is not worthwhile. For DELIVERY further improvements are limited by an output dependence in the ORDER LINE table. The STOCK LEVEL transaction is limited by dependences on the cursor used to scan the ORDER LINE table.

5.4 Scaling Intra-Transaction Parallelism

In Figure 20 we see the performance of the fully optimized transactions as the number of CPUs is varied. The SEQUENTIAL bar represents the unmodified benchmark running on a single core of an 8 core chip multiprocessor, while the 2 CPU, 4 CPU and 8 CPU bars represent the execution of full TLS-optimized executables running on 2, 4 and 8 CPUs.
Fig. 20. Performance of optimized benchmark while varying the number of CPUs.
Large improvements in transaction latency can be obtained by using 2 or 4 CPUs, although
the additional benefits of using 8 CPUs are small.

Each bar is divided into subdivisions which show what each CPU is doing for each cycle
of execution. The subdivisions are explained in Table III. In Figure 20 we have normalized
all bars to the 8 CPU case so that the subdivisions of each bar can be directly compared.
This means that the sequential breakdown shows one CPU executing and seven CPUs
idling, the 2 CPU breakdown shows two CPUs executing and six CPUs idling, etc.

The New Order, New Order 150 and Delivery Outer bars show that very little
time was spent on failed speculation—this means that our performance tuning was success-
ful at eliminating performance-critical data dependences for those transactions. The
Delivery transaction has some failed speculation due to a dependence in updating the
Order Line table, and the Stock Level transaction has failed speculation due to a
dependence in the cursor used to scan the Order Line table. As the number of CPUs
increases there is a nominal increase in both failed speculation and time spent awaiting
the latch used to serialize isolated undoable operations: as more epochs are executed concur-
rently, contention increases for both shared data and the latch. As the number of CPUs
increases there is also an increase in time spent awaiting cache misses: spreading the exe-

Incrementally Parallelizing Database Transactions with Thread-Level Speculation

... execution of the transaction over more CPUs decreases cache locality, since the execution is partitioned over more level 1 caches. We also see a much larger increase in the number of cache misses for the STOCK LEVEL transaction—a large amount of cache state can be invalidated when speculation fails, leading to increased cache misses. The negative effects of cache misses overwhelm any parallel overlap in the ORDER STATUS transaction, resulting in a slowdown as the number of CPUs increases.

The dominant component of the bars in NEW ORDER and DELIVERY is idle time, for three reasons. First, in the SEQUENTIAL, 2 CPU and 4 CPU case we show the unused CPUs as idle to allow direct comparison with the other bars. Second, the loop that we parallelized in the transaction only covers 78% of the transaction's execution time for NEW ORDER, and 63% for DELIVERY: during the remaining time only one CPU is in use. Third, TPC-C specifies that both transactions will deal with orders which contain between 5 and 15 items, which means that on average each transaction will have only 10 epochs—this means that as we execute the last epochs in the loop load imbalance will leave CPUs idling. The effects of all three of these issues are magnified as more CPUs are added. To see the impact of reducing this idle time, we modified the invocation of the NEW ORDER transaction so that each order contains between 50 and 150 items (which is the NEW ORDER 150 transaction). We found that this modification decreases the amount of time spent idling, and does not significantly affect the trends in cache usage or failed speculation.

Figure 20 shows a performance trade-off: devoting more CPUs to executing a single transaction improves performance, but results in increased contention, a decrease in cache locality, and/or diminishing returns due to a lack of available parallelism, thus resulting in diminishing returns as more CPUs are added. One of the strengths of using TLS for intra-transaction parallelism is that it can be enabled or disabled at any time, and the number of CPUs can be dynamically tuned. The database system’s scheduler can dynamically increase the number of CPUs available to a transaction if CPUs are idling, or to speed up a transaction which holds heavily contended locks. If many epochs are being violated, and thus the intra-transaction parallelism is providing little performance benefit, then the scheduler could reduce the number of CPUs available to the transaction. If the transaction compiler simply emitted a TLS parallel version of all loops in transactions then the scheduler could use sampling to choose loops to parallelize: the scheduler could periodically enable TLS for loops which are not already running in parallel, and periodically disable TLS for loops which are running in parallel. If the change improves performance then the scheduler can make it permanent.

5.5 Impact of Each Optimization

In Figure 21 we see the results of the optimization process for the benchmarks which sped up on a four CPU system. In this experiment the breakdown of the bars is normalized to a four CPU system, and so of the SEQUENTIAL bars is Idle, since three of the four CPUs are idling during the entire execution. The NO OPTIMIZATIONS bars show what happens if we parallelize the transaction and make no other optimizations—the existing data dependences in the DBMS prevent any parallelism from being exploited, and the fact that we have taken a sequential transaction and run it on four CPUs has reduced cache locality, causing it to slow down between 5 and 8%.

Consider the NEW ORDER transaction in Figure 21(a). The major source of failed speculation in our newly-parallelized transaction are the reads and writes to latches; hence we...
perform the lazy latch optimization described in Section 4.1.1. This optimization fixes the first performance bottleneck, and exposes the next bottleneck which is in the lock code. The first optimization also results in a slight slowdown, since the next bottleneck merely delays detection of failed speculation (as illustrated in Figure 10)—hence more execution has to be rewound.

Once we have eliminated latches as a bottleneck in NEW ORDER, the next bottleneck exposed is in the locking subsystem. We remove the lock bottleneck by implementing lazy locks from Section 4.1.2. We continue to remove the bottlenecks one by one: applying
the code template from Figure 9 to \texttt{db\_malloc} and the \texttt{pin\_page} operation, parallelizing the free cursor pool, removing dependence causing error checks (Section 4.5), adding padding to avoid violations due to false sharing (Section 4.6), removing the “last page referenced” pointer from the B-tree search code (Section 4.3), delaying the generation of log entries until epochs are ready to commit (Section 4.2), and parallelizing the assignment of locker ids.

It is tempting to look at Figure 21(a) and conclude that the most important optimization was parallelizing the buffer pool, since adding this optimization caused the execution time to drop by 32%. However, this is not the case since the impact of the optimizations is cumulative. If we take the NO OPTIMIZATIONS build and just enable the buffer pool opti-
mization then the normalized performance is 0.98. Instead, Figure 21 implies that the iterative optimization process which we used works well—as the database system programmer removes performance limiting dependences performance gradually improves (and exposes new dependences). Removing dependences decreases the time spent on failed execution, and improves performance.

Figure 21(b) shows the same experiment performed on the larger NEW ORDER 150 transaction. This transaction mirrors the NEW ORDER transaction, except the idling caused by load imbalance is no longer dominant with more epochs.

Figures 21(c), (d) and (e) show the same experiment for the DELIVERY, DELIVERY OUTER, and STOCK LEVEL transactions. The order in which each bottleneck dependence becomes dominant varies from transaction to transaction. Also, not all of the bottlenecks found in NEW ORDER need to be removed to get the best performance out of these three transactions—for the STOCK LEVEL transaction performance actually degrades from 0.40 to 0.47 when the additional code to eliminate bottlenecks experienced by NEW ORDER is applied. STOCK LEVEL also shows that applying TLS can hurt performance: in the early rounds of optimization the transaction suffers dramatically from the decreased cache locality introduced by parallel execution, and there is insufficient parallel overlap to compensate for this effect. Overall, in DELIVERY, DELIVERY OUTER, and STOCK LEVEL the iterative process works quite well, resulting in significant performance improvements for each transaction.

We have shown an iterative optimization process in action. When should the iteration stop? Consider the FAILED segment of the bars in Figure 21. Note that eliminating a dependence avoids a violation, and hence only improves the performance of the FAILED portion of execution. The database system programmer chooses to stop when any potential gains in performance outweigh the perceived difficulty of eliminating the next bottleneck data dependence.

Fig. 21. Continued.
6. CONCLUSIONS

Chip multiprocessing has arrived, as evidenced by recent products (and announced road maps) from Intel, AMD, IBM and Sun Microsystems. While the database community has long embraced parallel processing, the fact that an application must exploit parallel threads to tap the performance potential of these additional CPU cores presents a major challenge for desktop applications. Processor architects have responded to this challenge through a new mechanism—thread-level speculation (TLS)—that enables optimistic parallelization on chip multiprocessors. Fortunately for the database community, although TLS was originally designed to overcome the daunting challenge of parallelizing desktop applications, it also allows us to tap new forms of parallelism within a DBMS that had previously been too painful to consider.

In this article, we have focused on one such opportunity enabled by TLS: exploiting intra-transaction parallelism. Our experimental results demonstrate that we can speed up the latency (not just the throughput) of three of the five transactions in TPC-C by 44–66% by exploiting TLS on a chip multiprocessor with four CPU cores. TLS allows the database’s scheduler to use CPU cores to improve latency when throughput is not the primary concern. In contrast with previous approaches to exploiting intra-transaction parallelism, we place almost no burden on the transaction programmer (they merely demarcate epoch boundaries). In the future this burden could easily be shifted to the transaction compiler. Although changes to the DBMS code are required to achieve this benefit, they affected less than 1200 out of 180,000 lines of code in BerkeleyDB, they were implemented in roughly a month by a graduate student, and we expect that they would generalize to other DBMSs. We hope that these promising results will inspire database researchers to find other opportunities for exploiting untapped parallelism through TLS.
