

# Matching Trajectories of Anatomical Landmarks under Viewpoint, Anthropometric and Temporal Transforms

Alexei Gritai, Yaser Sheikh, Cen Rao and Mubarak Shah, *Fellow, IEEE*

## Abstract

An approach is presented to match imaged trajectories of anatomical landmarks (e.g. hands, shoulders and feet) using semantic correspondences between human bodies. These correspondences are used to provide geometric constraints for matching actions observed from different viewpoints and performed at different rates by actors of differing anthropometric proportions. The fact that the human body has approximate anthropometric proportion allows innovative use of the machinery of epipolar geometry to provide constraints for analyzing actions performed by people of different sizes, while ensuring that changes in viewpoint do not affect matching. In addition, for linear time warps, a novel measure, constructed only from image measurements of the locations of anatomical landmarks across time, is proposed to ensure that similar actions performed at different rates are accurately matched as well. An additional feature of this new measure is that two actions from cameras moving at constant (and possibly different) velocities can also be matched. Finally, we describe how dynamic time warping can be used in conjunction with the proposed measure to match actions in the presence of nonlinear time warps. We demonstrate the versatility of our algorithm in a number of challenging sequences and applications, and report quantitative evaluation of the matching approach presented.

## I. INTRODUCTION

In his landmark treatise titled *Human Actions*, [44], Ludwig Von Mises opens his first chapter with the statement, “*Human action is purposeful behavior*”. He states that actions ostensibly reflect the actor’s intention, conscious or unconscious. It is not surprising, therefore, that visual perception of actions is a critical cognitive function for interpreting the intention of an observed actor and for understanding the observer’s environment. As social entities, the ability to interpret

and predict the behavior of others is fundamental to normal human functioning. In fact, there is a growing body of evidence that humans might actually understand the actions of another individual in terms of the same neural code that they use to produce the same action themselves, [27]. It is for these reasons that the analysis of human actions is a subject of interest in a number of scientific communities such as philosophy [31], developmental psychology [55], economics [44] and recently in cognitive neuroscience [67], [11]. It is also why developing algorithms for action recognition must figure prominently in the pursuit of both machine intelligence and robotics.

Developing algorithms to recognize human actions has proven to be a significant challenge since it is a problem that combines the uncertainty associated with computational vision with the added whimsy of human behavior. Even without these two sources of variability, the human body has no less than 244 degrees of freedom ([74]) and modeling the dynamics of an object with such non-rigidity is not an easy task. Further compounding the problem, recent research into anthropology has revealed that body dynamics are far more complicated than was earlier thought, affected by age, ethnicity, class, family tradition, gender, skill, circumstance and choice, [29]. Human actions are not merely functions of joint angles and anatomical landmark positions, but bring with them traces of the psychology, the society and culture of the actor. Thus, the sheer range and complexity of human actions makes developing action recognition algorithms a daunting task. To develop computer algorithms for analyzing actions, it is important to identify properties that are expected to vary according to a set of transformations with each observation of an action, but which should not affect recognition:

**Viewpoint** Except in specific application, it is unreasonable, in general, to assume that the viewpoint from which actions are observed would remain constant across different observations of that action. Thus, it is important that algorithms for action recognition exhibit stability in recognition despite large changes in viewpoint. The relationship of action recognition to object recognition was observed by Rao and Shah in [58], and developed further by Parameswaran and Chellappa in [52], [51], Gritai *et al* in [3] and by Yilmaz and Shah in [73]. In these papers, the importance of view invariant recognition has been stressed, highlighting the fact that, as in object recognition [68], the vantage point of the camera should not affect recognition. The projective and affine geometry of multiple views is well-understood, see [35], and various invariants have

been proposed. There has also been some discussion of viewpoint variance and invariance in cognitive neuroscience in the context of both object and action recognition, [68], [23]. In the proposed approach, accurate matching in the presence of varying viewpoint is a central problem which we address by using geometric relationships between the two observed executions of an action.

**Anthropometry** In general, an action can be executed, irrespective of the size or gender of the actor. It is therefore important that action recognition be unaffected by “anthropometric transformations”. Unfortunately, since anthropometric transformations do not obey any known laws, formally characterizing invariants is impossible. However, empirical studies have shown that these transformations are not *arbitrary* (see [56]). The study of human proportions has a great tradition in science, from the ‘Golden Sections’ of ancient China, India, Egypt and Greece down to renaissance thinkers like Leonardo Da Vinci (the Vitruvian Man) and Albrecht Durer, with modern day applications in Ergonomics and human performance engineering. We provide a functional definition of anthropometric transforms making implicit use of the ‘laws’ governing human body proportions to provide geometric constraints for matching. Instead of using a single point representation, we explore the use of several points on the actor for action recognition, and use geometric constraints with respect to two *actors* performing the action instead of two camera *views*. This innovative use of geometry allows two interesting results for the recognition of actions. The first result provides a constraint to measure the dissimilarity of the posture of two actors viewed in two images. The second result extends this first constraint to globally measure dissimilarity between two actions.

**Execution Rate** With rare exceptions such as synchronized dancing or army drills, actions are rarely executed at a precise rate. Furthermore, the cause of temporal variability can be two fold, caused by the actor or possibly by differing camera frame-rates. It is desirable, therefore, that action recognition algorithms remain unaffected by some set of temporal transformations. Definition of this set of temporal transformations is dependent on application. In this paper, we propose an approach that assumes that only linear temporal transformations in time can occur, and performs detection under this assumption. Under this assumption we also propose a new metric that can match a model action to a test action despite constant velocity motion of the

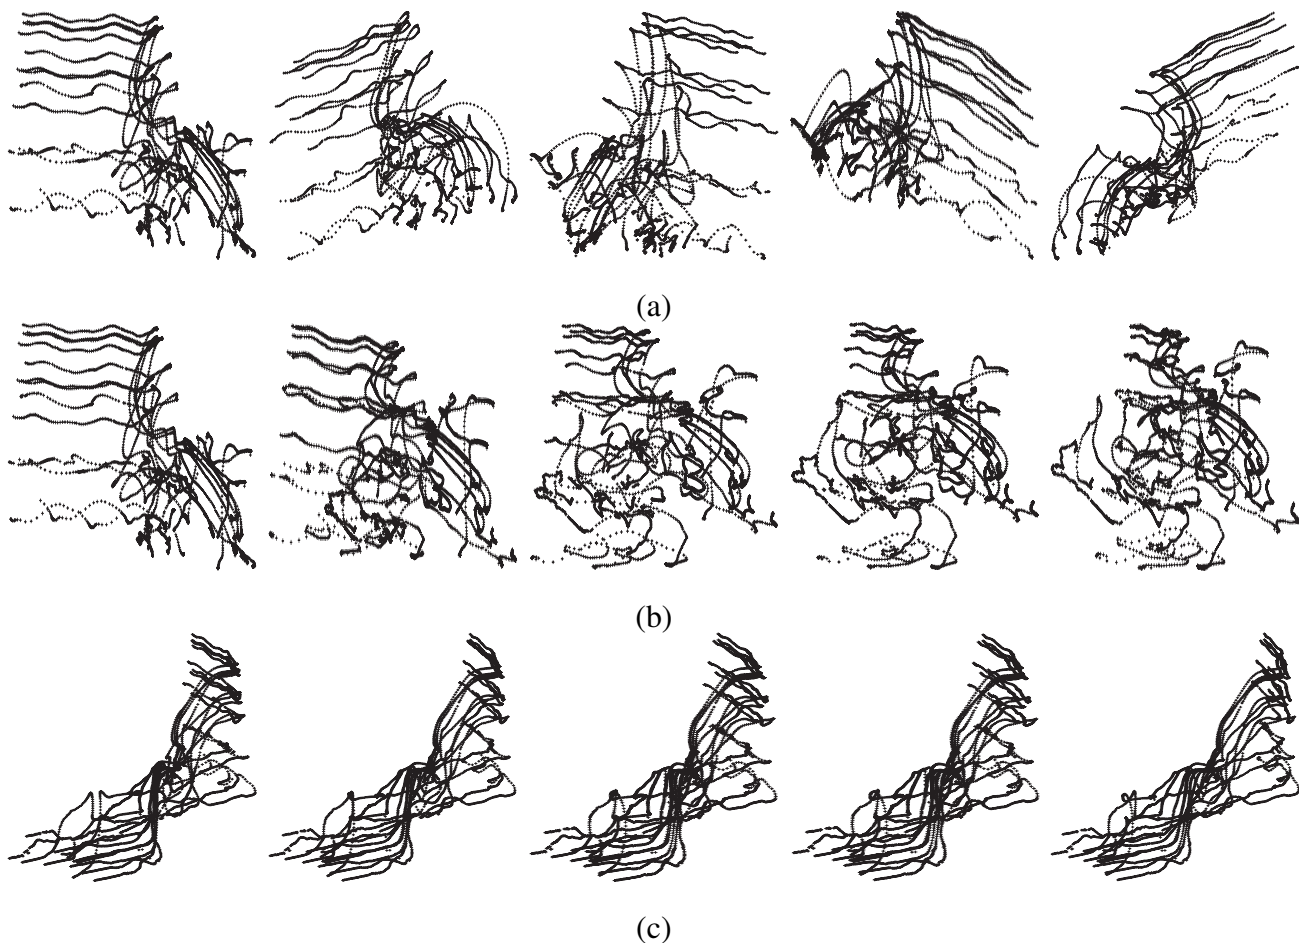

Fig. 1. Trajectories of anatomical landmarks of the same action under different types of transformation. The first row (a) presents the trajectories under different viewpoint transformations, the second row (b) under anthropometric transformations, and the third row (c) demonstrates the same trajectories obtained with different camera velocities along the  $X$ -direction.

camera. However, in some applications of action recognition the assumption of temporal linear transformation might not be acceptable. To handle general non-linear temporal transformations we utilize Dynamic Time Warping (DTW) for matching, which ensure only that the temporal order is preserved.

In this paper, we decouple of the problem of tracking anatomical landmarks in images and the problem of matching the trajectories generated by a tracking algorithm. Given the trajectories of different anatomical landmarks of actors on a query (or test) action and a model (or pattern) action, we present a novel dissimilarity measure that determines whether the trajectories in

the query video match the model action, allowing for three sets of transformations: viewpoint transformations, anthropometric transformations and temporal transformations. Figure 1 shows trajectories from the same action as captured under these different transformations. The algorithm, designed for illustration purpose, makes use of a measure that we demonstrate, both theoretically and empirically, to be able to match actions despite changes in the viewpoint of the actors to the camera. This measure is computed by looking at the eigenvalues of a matrix constructed from image measurements of anatomical landmarks. We propose a functional definition of the class of anthropometric transformations and use this definition to demonstrate that the measure defined is also stable to changes in the anthropometry of the actors involved. This is also demonstrated empirically during experimentation. We then use the proposed measure with DTW to determine whether two actions are the same, except by a linear transformations of time. The assumption of a stationary camera is then lifted, by allowing the cameras to move with constant velocity. We define a novel measure to match actions in this scenario which inherits all the properties of the earlier measure (stability to changes in viewpoint and anthropometry and use for temporally invariant matching). We demonstrate the application of the proposed approach in many diverse scenarios such as action synchronization, action recognition and gait analysis. Using motion capture data we also quantitatively analyze the proposed measure, verifying the properties described in the paper.

The rest of the paper is organized as follows. We situate our work in context of previous research in Section II and describe our representation and notation in Section III. We then unfold the three different layers of analysis successively for viewpoint transformations (Section IV), for anthropometric transformations (Section V) and finally temporal transformations (Section VI). Results are presented in Section VII, followed by conclusions in Section VIII.

## II. LITERATURE REVIEW

Research on human action recognition through computer vision started in the late seventies, the earliest work probably being the PhD thesis of Herman, [36]. This work used a static representation, a stick figure in a single image, to analyze different postures of a person. The importance of dynamics was almost immediately realized and used in a series of papers in the the early eighties, [60], [6], [59]. Since then a large body of literature has accumulated studying different approaches to track, reconstruct and recognize human motion. Surveys of the area have

been regularly published including Aggarwal *et al*, [39] in 1994, Cedras and Shah, [22], in 1995, Ju [41] in 1996, Aggarwal and Cai, [4] and Gavrilu, [30], in 1999, Moeslund and Granum, [45], in 2001, Buxton, [19], and Wang, [42], in 2003, and finally Aggarwal and Park, [5] in 2004. Under Gavrilu's taxonomy of human motion analysis, methods can be roughly classified as image-based approaches or 3D approaches, i.e. methods that perform recognition directly from image measurements and those that try to recover and then analyze 3D information of human postures and dynamics. Typically in 3D approaches, models of human body and human motion are used and a projection of the model in a particular posture is then compared with each frame of the input video to recognize the action. The advantage of these approaches is that since a 3D model is explicitly used these methods are inherently view invariant. However, they are usually computationally quite expensive, [37] and 3D recovery of the articulated objects is still a difficult problem. As a result, 3D approaches are therefore usually limited in some specific applications, such as athletic analysis and sign language recognition [20], [26].

In image-based approaches only 2D measurements, such as optical flow, spatio-temporal gradients or point trajectories, are computed across a sequence of frames to recognize actions. An overwhelming majority of recent work in action recognition falls in this category. The methods proposed in this category can be further subdivided into two categories: (1) Feature based approaches and (2) 'Direct' approaches.

A whole slew of different features have been proposed and used. To recognize the temporal textures, the statistical features of optical flow such as mean flow magnitude, standard deviation, the positive and negative curl and divergence, are used in [54]. Other features to recognize human activities include region-based [25], [48], [54], [7], [43], temporal trajectory based [47], [72], [58], [32], part-based [10], [15], [41] or a combination of these [9], [34]. The approaches work based on features capturing either 2D shape or motion information. Usually, the recognition system involves some dissimilarity or similarity measurement between the activities and the models, such as the shape of the silhouettes, the trajectories of the moving hands, the point clouds from the body parts. Hidden Markov models have also been a popular tool in using these features for recognition following its success in speech recognition [71]. The earliest papers included work by Pentland *et al* [66], and Yamato *et al* [70]. More sophisticated models, such as Coupled Hidden Markov Model (CHHM)[50], Variable Length Markov Model (VLMM)[2], Layered Hidden Markov Model (LHMM) [49], stochastic context free grammar (SCFG) [13],

and Hierarchical Hidden markov model (HHMM) [46], [61], have been proposed for efficiently representing and recognizing activities from one or more persons. However these method require training data, and generally lack the capability of explaining the actions semantically.

Most recently, approaches loosely applying the paradigm of ‘direct’ methods proposed by Horn and Weldon in [38] which utilize the spatio-temporal information directly for motion analysis, have started to appear. The difference from feature based approaches is that image measurables are *directly* used for recognition. An approach based on the statistical features of spatio-temporal gradient direction is used for classifying human activities, e.g. walking, running, and jumping [21]. In [75], an action recognition system is proposed by matching the histogram of the optical flow generated by different actions. This approach is extended in [64], so that the spatio-temporal volumes of actions are exploited, and a correlation measure is computed for recognizing the same action from different video. The spatio-temporal information of actions is further used for detecting irregularities in images and in video [14]. In this work, a statistical framework is proposed for matching the patches containing actions in the video. In [69], Ke *et al* proposed using boosted classifiers to detect action events from the video from simple spatiotemporal filters. In [12] the silhouettes of the moving subjects are used in addition to the spatio-temporal information of the pixels. The method utilizes properties of the solution to the Poisson equation to extract space-time features such as local space-time saliency, action dynamics, shape structure and orientation, furthermore, these features are used for action recognition, detection and clustering.

The fundamental drawback of using such 2D image-based approaches, direct approaches in particular, is that they are viewpoint dependent. An intermediate category of approaches, including this paper, use image measurements, but exploit 3D constraint by exploiting the geometry of multiple views. Seitz and Dyer [63] used view-invariant measurement to find the repeating pose of walking people and the reoccurrence of position of turning points. Laptev [1] proposed using spatio-temporal points from the video to compute the fundamental matrix/homography, which are in temporal matrix format, and to detect the periodic motion once the transformation between video clips are obtained. Parameswaran and Chellappa proposed to use the 2D view invariant values, namely the cross ratio values, as the measure for matching the human actions from different viewing directions [53]. The multiple trajectories from the joints of a person are recorded, the pose during the action is matched with a canonical body pose, and the matching coefficients are used for representing the action, and the temporal variance of the actions is

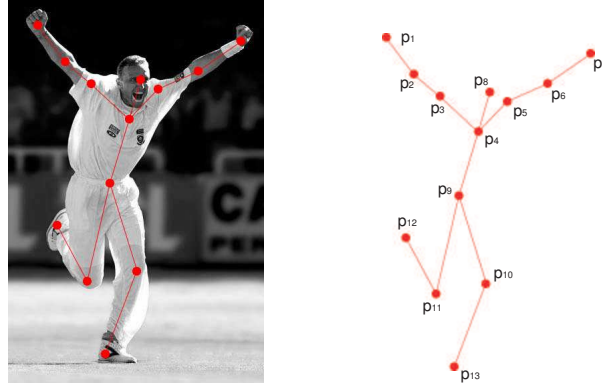

Fig. 2. Point-based representation. Johansson's experiments in [40] demonstrate that point-based representations contains sufficient information for action recognition, and figure illustrates the landmark positions in these experiments.

compensated using DTW. Finally, the actions are matched by comparing the coefficients of the actions.

### III. NOTATION

In this section we discuss our representation of actions and propose a novel matching scheme based on semantic correspondences between humans. Geometric constraints on these correspondences are used to analyze actions as they occur. The main concern in our work is the recognition of human activity performed by different people at varying rates in different environments or viewpoints.

#### A. Representation of actors and actions

The model of a moving body as a point is ubiquitous in the computer vision community. In our work, the input is the 2D motion of a set of 13 anatomical landmarks,  $\mathcal{L} = \{1, 2, \dots, 13\}$ , as viewed from a camera, see Figure 2. In [40], Johansson demonstrated that a simple point-based model of the human body contained sufficient information for the recognition of actions. Relying on this result, we represent the current pose and posture of an actor in terms of a set of points in 3D-space  $\hat{\mathbf{X}} = \{\mathbf{X}_1, \mathbf{X}_2 \dots \mathbf{X}_n\}$ , where  $\mathbf{X}_i = (X_i, Y_i, Z_i, \Lambda)^\top$  are homogenous coordinates and  $n \in \mathcal{L}$ . A *posture* is a stance that an actor has at a certain time instant, not to be confused with the actor's *pose*, which refers to position and orientation (in a rigid sense). Each point represents the spatial coordinate of an anatomical landmark (see [16]) on the human body as shown in

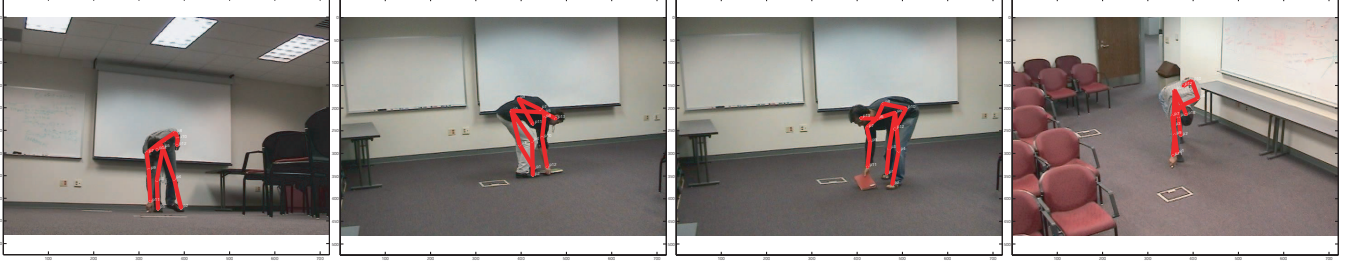

Fig. 3. Frames corresponding to ‘picking up’ in four sequences. The left-most frame corresponds to the model sequence, and the rest correspond to the test sequences. In each sequence, the actors are in markedly different orientations with respect to the camera, but in the same posture.

Figure 2. For the  $i$ th frame of the  $k$ th camera, the imaged pose and posture are represented by  $\hat{\mathbf{U}}^k = \{\hat{\mathbf{u}}_1^k, \hat{\mathbf{u}}_2^k \dots \hat{\mathbf{u}}_m^k\}$ , where  $\hat{\mathbf{u}}_i^k = \{\mathbf{u}_{(i,1)}^k, \mathbf{u}_{(i,2)}^k \dots \mathbf{u}_{(i,n)}^k\}$ ,  $\mathbf{u}_{(i,j)}^k = (u_{(i,j)}, v_{(i,j)}, \lambda)^\top$  and  $m$  is the number of frames.  $\hat{\mathbf{X}}$  and  $\mathbf{u}^k$  are related by a  $4 \times 3$  projection matrix  $\mathbf{C}^k$ , i.e.  $\mathbf{u}^k = \mathbf{C}^k \hat{\mathbf{X}}$ . As will be seen presently, nine imaged points on human body are required in each frame of video and, at least, one of them must correspond to the body part directly involving in action. We refer to each entity involved in an *action* as an *actor*. An *action element*,  $\hat{\mathbf{u}}_t$ , is the portion of an action that is performed in the interval between frames  $t$  and  $t+1$ . Each action is represented as the set of action elements. For a comparison of other representations to this one the reader is referred to [30].

#### IV. VIEWPOINT TRANSFORMATIONS

Figure 3 shows the same action (‘picking up a book’) from 4 different points of view. Although the same action is being performed the distribution of points on the image differs significantly. As has been observed previously for object recognition, it is usually unreasonable to place restrictions on the possible viewpoint of the camera, and action recognition algorithms should therefore demonstrate *invariance* to changes in viewpoint. Invariants are properties of geometric configurations that are unaffected under a certain class of transformations. It is known that view-invariants do not exist for general 3D point sets, [18]. However, there are useful properties that are not strictly invariant, but remain stable over most transformations. We now describe a measure to match actions that is based on one such property. Assuming two frames are temporally aligned (until Section VI), the labels associated with each anatomical landmark provide point-to-point

correspondence between the two postures. The constraint we use is that if the two imaged point sets match they are projections of the same structure in 3D. In [58], a rank constraint based dissimilarity measure was described that was stable to camera viewpoint changes. The main drawback of this dissimilarity measure was the assumption of affine cameras. To remove this assumption, instead of using this factorization based rank constraint, we use a constraint derived from epipolar geometry. For the projective camera model, the fundamental matrix (a  $3 \times 3$  matrix of rank 2),  $\mathbf{F}$ , is defined between corresponding points by

$$\begin{bmatrix} u \\ v \\ 1 \end{bmatrix}^T \mathbf{F} \begin{bmatrix} u' \\ v' \\ 1 \end{bmatrix} = 0, \quad (1)$$

for the pair of matching points  $(u, v) \leftrightarrow (u', v')$  in trajectories, observed from two different viewpoints. Clearly, given a fundamental matrix, we can use Equation 1 to measure the dissimilarity between two trajectories, so that the squared residual for all points is minimized. By rearranging Equation 1 a dissimilarity measure can also be defined directly from the trajectory values themselves (without explicitly computing  $\mathbf{F}$ ). Given at least 9 point matches, we have,

$$\mathcal{A}\mathbf{f} = \begin{bmatrix} u'_1 u_1 & u'_1 v_1 & u'_1 & v'_1 u_1 & v'_1 v_1 & u'_1 & u_1 & v_1 & 1 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ u'_t u_t & u'_t v_t & u'_t & v'_t u_t & v'_t v_t & u'_t & u_t & v_t & 1 \end{bmatrix} \mathbf{f} = 0, \quad (2)$$

where  $\mathbf{f} = [f_{11} \ f_{12} \ f_{13} \ f_{21} \ f_{22} \ f_{23} \ f_{31} \ f_{32} \ f_{33}]^T$  is the fundamental matrix vectorized in row-major order. We refer to  $\mathcal{A}$  as the observation matrix, which is constructed using only the coordinates of points of corresponding 2D trajectories. Since Equation 2 is homogenous, for a solution of  $\mathbf{f}$  to exist, matrix  $\mathcal{A}$  must have rank at most eight, and this fact can be exploited to measure dissimilarity. Of course, due to the noise or the matching error, the rank of matrix  $\mathcal{A}$  may not be exactly eight. The condition number of  $\mathcal{A}$ , i.e. the ratio of the smallest singular value,  $\sigma_9$ , to the largest singular value,  $\sigma_1$ , of  $\mathcal{A}$  provides the algebraic error of corresponding points in matrix  $\mathcal{A}$ . This ratio can be used to measure the match of two trajectories,

$$\kappa = \frac{\sigma_9}{\sigma_1}. \quad (3)$$

It should be noted that the observation matrix  $\mathcal{A}$ , and therefore this dissimilarity metric, is constructed only from measured image position. In addition to viewpoint changes caused by

different camera locations, anthropometric transformations are also expected, caused by different actors, which is discussed next.

## V. ANTHROPOMETRIC TRANSFORMATIONS

Both body size and proportion vary greatly between different races and age groups and between both sexes. However, while human dimensional variability is substantial, several anthropometric studies (see [28], [17], [8]) empirically demonstrate that it is not *arbitrary*. These studies have tabulated various percentiles of the dimensions of several human anatomical landmarks. In this paper, we conjecture that for a large majority of the human population the proportion between human body parts coupled with a rigid transformation in 3D space can be captured by a projective transformation of  $\mathbb{P}^3$ , projective 3-space [35].

**Conjecture 1** Suppose the set of points describing actor  $A_1$  is  $\hat{\mathbf{X}}$  and the set of points describing actor  $A_2$  is  $\hat{\mathbf{Y}}$ . The relationship between these two sets can be described by a matrix  $\mathcal{M}$  such that

$$\mathbf{X}_i = \mathcal{M}\mathbf{Y}_i \quad (4)$$

where  $i = 1, 2 \dots n$  and  $\mathcal{M}$  is a  $4 \times 4$  non-singular matrix.

This was empirically supported using the quite representative data in [16] (Table 5-1 and 5-2 which record the body dimensions of male and female workers between the ages of 18 and 45). For the most extreme case, between the dimensions of the ‘5th percentile woman’ and the ‘95th percentile man’, where a mean error of 227.37 mm was found before transformation, a mean error of 23.87 mm was found after applying an appropriate transformation. Using this property, geometric constraints can be used between the imaged points,  $\hat{\mathbf{x}}$  and  $\hat{\mathbf{y}}$  of the two actors. The transformation  $\mathcal{M}$  simultaneously captures the different pose of each actor (with respect to a world coordinate frame) as well as the difference in size/proportions of the two actors.

### A. Postural Constraint

If two actors are performing the same action, the postures of each actor at a corresponding time instant with respect to the action time coordinate should be similar. Thus an action can be

recognized by measuring the dissimilarity of posture at each corresponding time instant.

**Proposition 1** If  $\hat{\mathbf{x}}_t$  and  $\hat{\mathbf{y}}_t$  describe the imaged posture of two actors at time  $t$ , a matrix  $\mathcal{F}$  can be uniquely associated with  $(\hat{\mathbf{x}}_t, \hat{\mathbf{y}}_t)$  if the two actors are in the same posture.

It is known (pg. 247 Section 9.2, [35]) that for uncalibrated cameras the ambiguity of structure is expressed by such an arbitrary non-singular projective matrix. If two actors are in the same posture, the only difference between their point-sets is a projective relationship (Conjecture 1). Thus, if an invertible matrix  $\mathcal{P}$  exists between  $\mathbf{X}$  and  $\mathbf{Y}$ , i.e.  $\mathbf{Y} = \mathcal{P}\mathbf{X}$ , a *fundamental* matrix is uniquely determined by  $\mathbf{x}^\top \mathcal{F} \mathbf{y} = 0$  (Theorem 9.1 [35]).<sup>1</sup> It is important to note that the matrix  $\mathcal{F}$  does not capture only the relative positions of the cameras as does the fundamental matrix  $\mathbf{F}$ , but instead the relative poses of the actors and the relative anthropometric transformation between the actors.

Since the labels of each point are assumed known, *semantic* correspondences (i.e. the left shoulder of  $A_1$  corresponds to the left shoulder of  $A_2$ ) between the set of points are also known. Proposition 1 states that the matrix computed using these semantic correspondences between actors inherently captures the difference in anthropometric dimensions and the difference in pose. This point is illustrated in Figure 4. The matrix  $\mathcal{F}$ , computed between the actors, captured an anatomical relationship between the actors as well as the different views of the actors. The result is that the dissimilarity measure, described in Section IV, remains stable despite changes in anthropometry of the actors. Since the anthropometric proportions of actor can be expected to remain the same over short periods of time this fact can be used to provide an even stronger constraint which we now describe.

### B. Action Constraint

Along with the frame-wise measurement of postural dissimilarity, it is observed here that a strong *global* constraint can be imposed on the point sets describing two actors if they are performing the same action.

<sup>1</sup>Points that lie on the line joining the principal points are excluded.

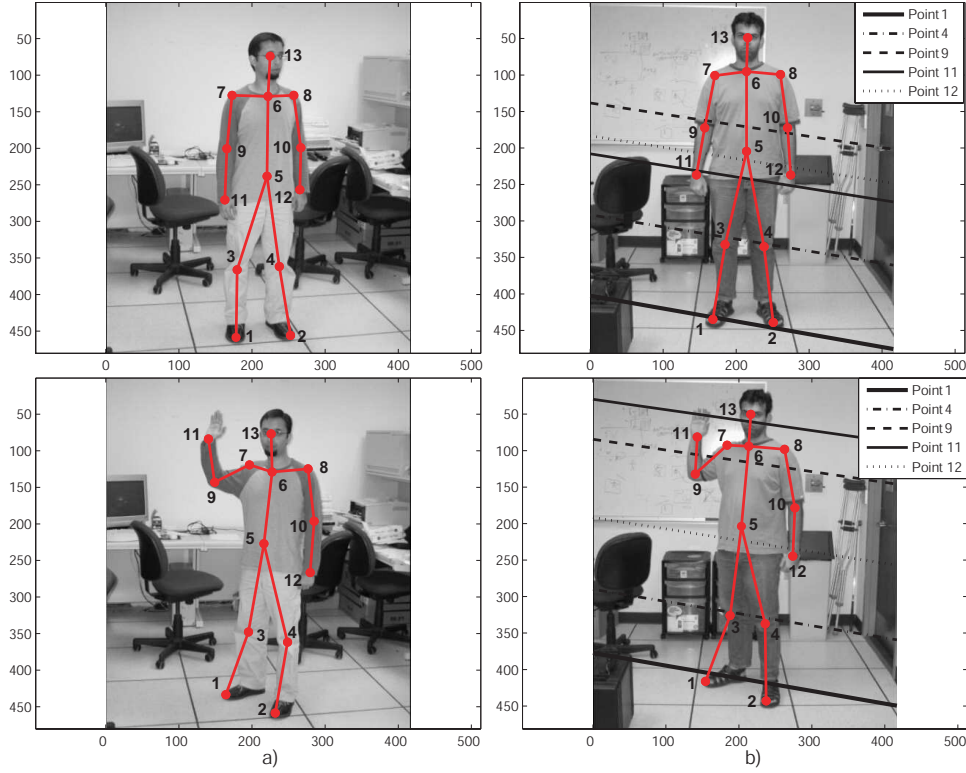

Fig. 4. The matrix  $\mathcal{F}$  can capture the relationship between body landmarks of two different actors of different height, weight, etc. but in the same posture. It captures the variability in proportion as well as the change in viewpoint. a) Actor 1 in two frames of the model video. b) Actor 2 in the corresponding frames of the test video. The landmark correspondences in first frames of model and test video (the first row) were used to compute the matrix  $\mathcal{F}$ . The image on right in (b) shows epipolar lines corresponding to landmarks in the image on right in (a). It is clear that the landmarks in the test video lie close to the corresponding epipolar lines; in particular, the epipolar lines pass close to their corresponding landmarks 9 and 11 after the right hand of the Actor 2 was moved.

**Proposition 2** For an action-element  $\hat{\mathbf{u}}_t$ , the fundamental matrices associated with  $(\hat{\mathbf{x}}_t, \hat{\mathbf{y}}_t)$  and  $(\hat{\mathbf{x}}_{t+1}, \hat{\mathbf{y}}_{t+1})$  are the same if both actors perform the action element defined by  $\hat{\mathbf{u}}_t$ .

Based on Conjecture 1, we can say that  $\mathcal{M}$  remains the same between time  $t$  and  $t+1$ . In other words,  $\mathcal{M}$  determines  $\mathbf{Y}$  with respect to  $\mathbf{X}$  and does not depend on the motion of  $\mathbf{X}$ . Since  $\mathcal{M}$  is the same then the matrices,  $\mathcal{F}_t$  and  $\mathcal{F}_{t+1}$ , corresponding to  $(\hat{\mathbf{x}}_t, \hat{\mathbf{y}}_t)$  and  $(\hat{\mathbf{x}}_{t+1}, \hat{\mathbf{y}}_{t+1})$  are the same (p.235 Result 8.8, [35]).

What this means is that if both individuals perform the same action-element between frame  $f_t$  and frame  $f_{t+1}$ , the transformation that captured the difference in pose and dimension between the

two actors remains the *same*. As a direct consequence, the subspace spanned by the measurement matrix  $A$  also remains the same and this suggests that if a measurement matrix were constructed using *all* the corresponding points over the entire action  $\hat{A} = [A_1, A_2, \dots, A_k]$ ,  $\kappa_{\hat{A}}$  can be used as a global measure of *action* dissimilarity. The second row of Figure 4 illustrates this. Both actors of clearly different anatomical proportion perform the same action element (they moved their right foot back and raised their right hand). The matrix  $\mathcal{F}$  computed between the actor in their original postures was used to compute epipolar lines after the execution of the action element. Clearly, to the extent that the same action element was performed, the geometric relationship is preserved. Thus, instead of considering the action as the successive motion of 13 points over  $n$  frames, each action is considered to be a cloud of  $13n$  points, each point having a unique spatio-temporal index (see Figure 1). However, the analysis thus far has assumed that temporal transformations had been accounted for. In practice, temporal transformations, small or large, always exist. We now describe how to compensate for these transformations during action analysis.

## VI. TEMPORAL TRANSFORMATIONS

While invariance to change in viewpoint is required in action analysis due to the imaging process, invariance to temporal transformations is needed due to the nominal uniqueness of each actor's execution of an action. In this paper, we describe matching algorithms that are stable under two types of transformations. First, we describe a new metric that can match actions despite linear transformation in time (scaling and shifts). We show that this metric can also match actions despite constant velocity motion of the camera. This model works effectively for many applications, particularly when the pattern is of a short duration. It was found that the use of a linear model is also appropriate for *coarse* matching and synchronization. Second, we describe a more general approach, where the temporal transformation may be highly nonlinear, using DTW to compensate for temporal transformations. In this case, there is no clearly defined class of temporal transformations, except that temporal order must be preserved during the transformation.

### A. Linear transformation and Constant Velocity

A linear transformation of time can be expressed as,

$$t' = a_1 t + a_2, \quad (5)$$

$$\mathcal{A}_{\mathbf{T}}f = \begin{bmatrix} u'_1 t_1 & u'_1 u_1 & u'_1 v_1 & u'_1 t_1 v_1 & u'_1 t_1 u_1 & u'_1 & v'_1 t_1 & v'_1 u_1 & v'_1 v_1 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ u'_n t_n & u'_n u_n & u'_n v_n & u'_n t_n v_n & u'_n t_n u_n & u'_n & v'_n t_n & v'_n u_n & v'_n v_n \\ & & & & & & & & \\ & v'_1 t_1 v_1 & v'_1 t_1 u_1 & v'_1 & t_1 & u_1 & v_1 & t_1 v_1 & t_1 u_1 & 1 \\ & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ & v'_n t_n v_n & v'_n t_n u_n & v'_n & t_n & u_n & v_n & t_n v_n & t_n u_n & 1 \end{bmatrix} f = 0, \quad (6)$$

### B. Non-linear Transformation

DRAFT

(action) constraint need to be incorporated in computation of the dissimilarity measure. Applying a temporal window ( $k$  frames before and after the current one) for computation of dissimilarity measure between two agents provided a marked improvement.

To synchronize two signals  $I$  and  $J$  by DTW, a distance,  $\mathbf{E}$ , is computed to measure the misalignment between two temporal signals, where  $\mathbf{E}(i, j)$  represents the error of aligning signals (distance measure) up to the time instants  $t_i$  and  $t_j$  respectively. The error of alignment is computed incrementally using the formula:

$$\mathbf{E}(i, j) = \mathbf{dist}(i, j) + \mathbf{e}, \quad (7)$$

where

$$\mathbf{e} = \min \{ \mathbf{E}(i-1, j), \mathbf{E}(i-1, j-1), \mathbf{E}(i, j-1) \}.$$

Here  $\mathbf{dist}(i, j)$  captures the cost of making time instants  $t_i$  and  $t_j$  correspond to each other. The best alignment is then found by keeping track of the elements that contribute to the minimal alignment error at each time step and backward following a path from element  $\mathbf{E}(i, j)$  to  $\mathbf{E}(1, 1)$ .

Similar to [57], in our framework  $I$  and  $J$  are trajectories representing similar or different actions observed from distinct viewpoints, and by introducing  $\kappa(i, j)$  as the  $\mathbf{dist}(i, j)$ , the standard DTW becomes appropriate for action recognition and robust to view, anthropometric and temporal transformations.

## VII. EXPERIMENTAL RESULTS

To demonstrate the performance of the approach in this paper, we performed experiments both qualitatively in several challenging scenarios and quantitatively using motion capture data. All data used during recognition was in the form of image measurements from uncalibrated cameras. In the qualitative experiments we demonstrate the versatility of the proposed approach in solving a variety of problems including action recognition, video synchronization and gait analysis. We designed our experiments to test each ‘layer’ of analysis in isolation as well as experiments that demonstrate efficacy under all sources of variability.

### A. Qualitative Results

In this set of experiments, trajectories from an exemplar action were matched against trajectories from a longer test sequence. To match we manually marked the landmarks and computed

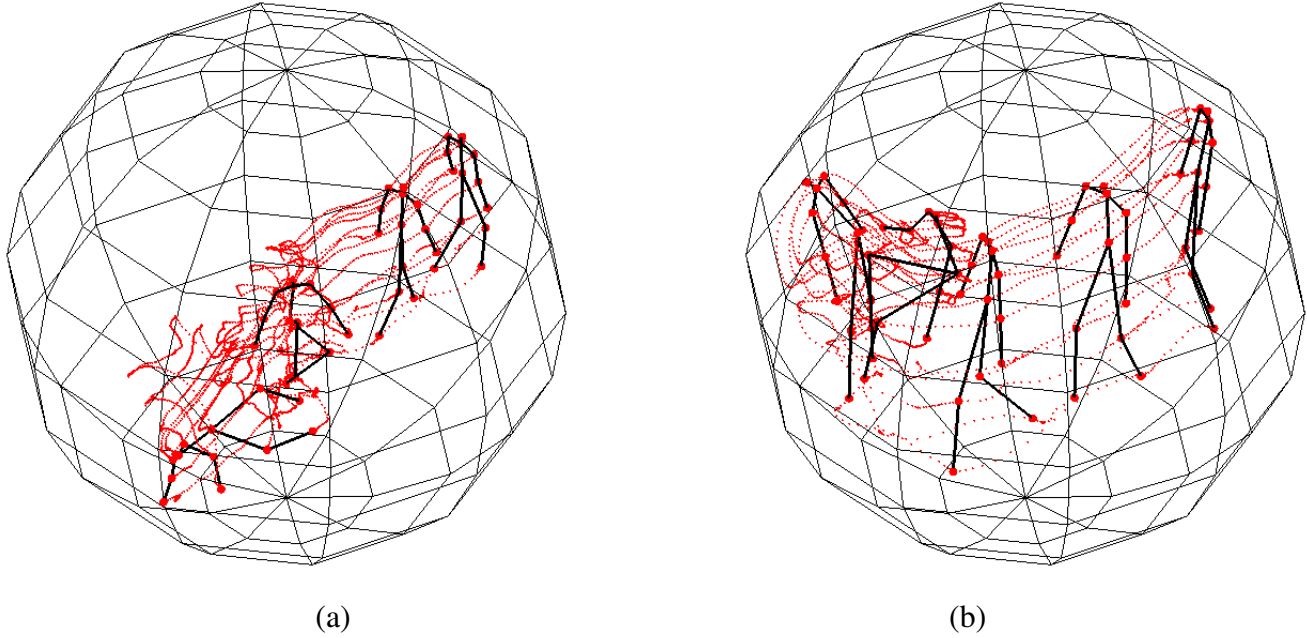

Fig. 5. Viewing spheres. (a) The action ‘getting up’ is viewed at regular intervals on a sphere around the action. (b) The action ‘Sit Down’ is viewed at regular intervals on a sphere around the action.

$\kappa$  at each frame number between the exemplar trajectories and an equally sized trajectory set (through temporal windowing) from the longer test sequence, centered around that frame number.

*1) Trajectory Matching:* In this experiment, actors performed a sequence of three actions: walking, picking up an object, and walking away. Videos were taken of two different actors as they performed this sequence with different orientations relative to the camera. The action of picking up an object was detected in each video by matching an exemplar sequence containing only the ‘picking up an object’ action. Figure 6 shows plots of the matching score against frame number. The value at each time location in the plots were obtained by matching the temporal neighborhood against the exemplar sequence. It can be seen that a distinct minimum occurs at the temporal location where the best match occurs. The corresponding frames at these minima are also shown in the figure.

The sensitivity of matching was also tested in a sequence containing four individuals walking. A test pattern of a single cycle of the distinctive ‘Egyptian’ gait was compared to each actor’s motion and the variation of the smallest singular value over time for each of the four actors is shown in Figure 7 (the odd-one-out is the third actor from the left). There are two points

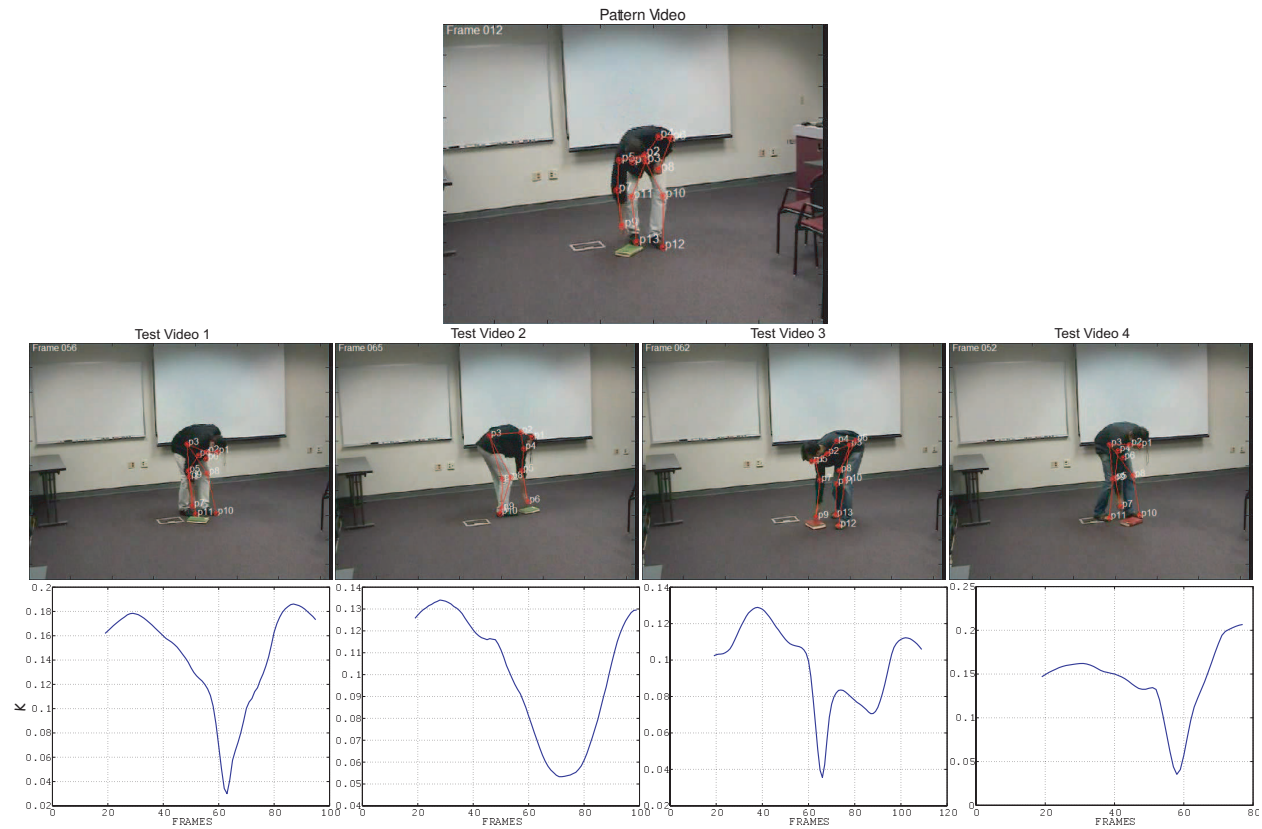

Fig. 6. Action matching from multiple views. Plots of the matching score against the frame number for four videos. Frames corresponding to the minima are shown for each video.

of interesting in this figure. First, since the posture involved in the ‘Egyptian’ gait is relatively distinct from the usual human gait the smallest singular value for the third actor is consistently larger and distinct from the other actors. Second, the sinusoidal nature of the plot clearly shows the periodicity that is associated with walking. In order to generate the plots, a cycle of one gait was matched against all other gait sequences.

2) *Video Synchronization*: Three actors jumped asynchronously in the field of view of a stationary camera. The objective in this experiment was to align the actors jumps and twists so that a new *synchronized* sequence could be rendered. The temporal transformation between actors was highly nonlinear, and DTW, with a 10-frame window around the current frame and  $\kappa$  as the distance measure, was used. Accurate synchronization was achieved and Figure 8 shows the result of synchronization with respect to the left-most actor using the proposed approach. The top row shows the original sequence and the bottom row shows the rendered sequence. The

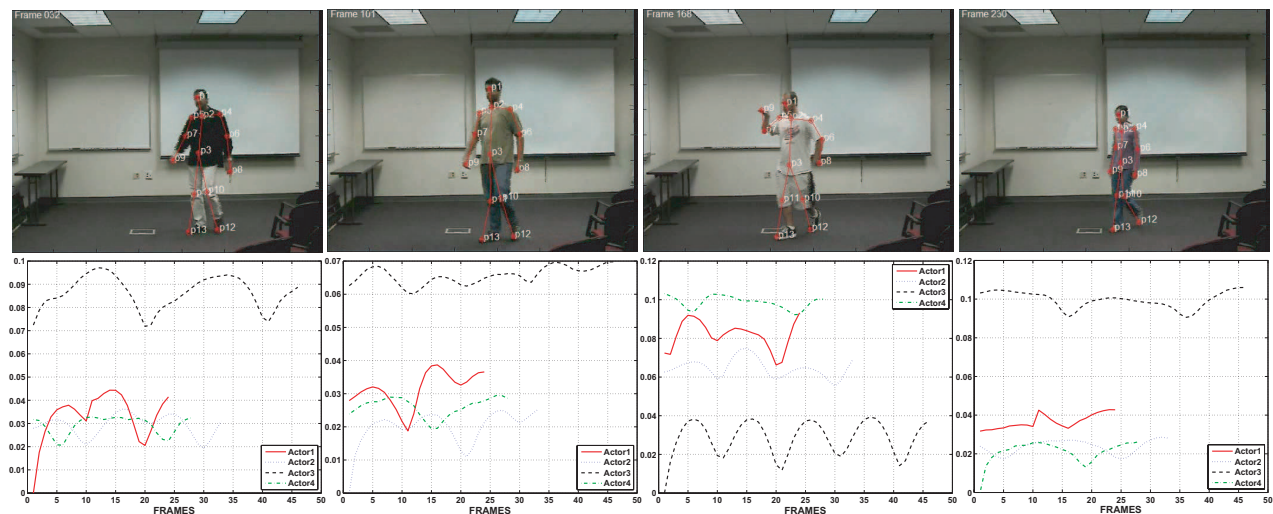

Fig. 7. Odd One Out. Actor three, the third figure from the left, corresponds to the actor performing the ‘Egyptian’ gait.

Fig. 8. Following the leader (the left-most actor). The top row shows four frames, 22, 25, 27, and 29 before synchronization. Notice the difference in postures of each actor within each single view. The bottom row shows corresponding frames (to the top row) from the rendered sequence after synchronization.

application of this sort of rendering includes post-processing of dance or exercise videos.

3) *Gait Analysis*: Videos of three actors were captured walking from two different viewpoints using two cameras, and, on average, each video was more than 200 frames in length. Six feature points, hands, knees and feet, were tracked. A short fragment (40 frames) was extracted from each video. The goal of this experiment was determining if the extracted fragment could be found in the video by computing the smallest singular value as the best dissimilarity measure.

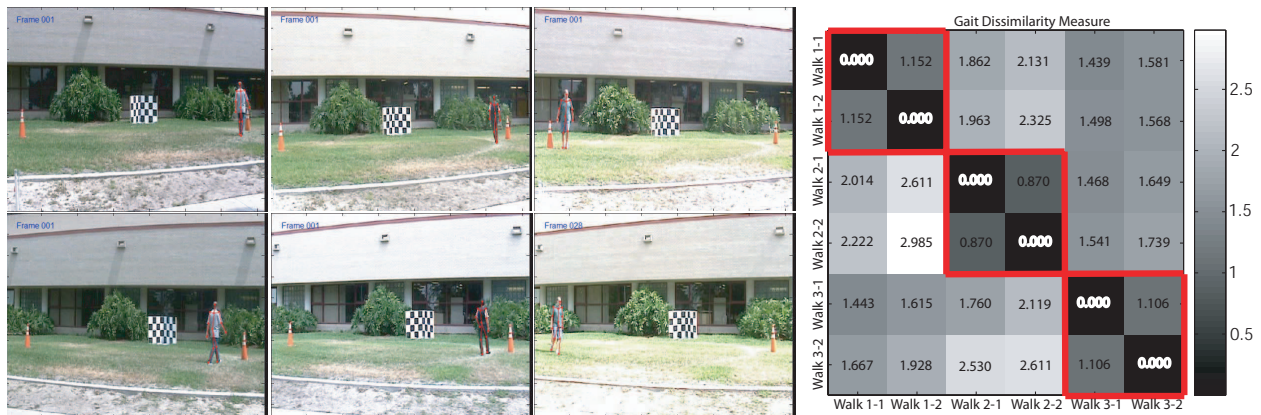

Fig. 9. Confusion Matrix for Gait Analysis. In the table the first and second columns correspond to the first actor in the first and second view respectively, and so on. The notation 1-1 refers to ‘Actor 1, View 1’ etc. Lower values correspond to the same actor’s gaits in different views (1-1 matches best with 1-2, 2-1 with 2-2, 3-1 with 3-2)

The table of Figure 9 shows the confusion matrix of each gait in each view. In the table the first and second columns correspond to the first actor in the first and second view respectively, and so on. The block-diagonal nature of the confusion matrix indicates that the distance between the gait of an actor in first view and in the second view is always lower than the gait of other actors in any view.

### B. Trajectory matching with Real Tracking Noise

In this experiment the landmarks tracks were generated using an improved version of body joints tracking algorithm [33]. In addition, we also manually marked the correct landmark positions to estimate the error of the joints tracking algorithm. The goal was to analyze the performance of the proposed method in a presence of the noise (detection error) with uncontrolled statistical parameters. The model action was 50 frames long and observed from the frontal view. The test actions were performed by four actors with anthropometric proportion significantly different from the actor who performed the model action. All test sequences consisted of the same set of actions, one of which was identical to the model action. The test actions 1, 2, 3 and 4 were 450, 524, 463 and 471 frames long, respectively. For each test action, all clips, starting from frame 1 and consisting of 50 consecutive frames, were compared to the model action. The first row of Figure 10 shows the results of detecting model action in the test actions. In order to demonstrate the error in these clips, the detection error of the selected landmarks in each frame

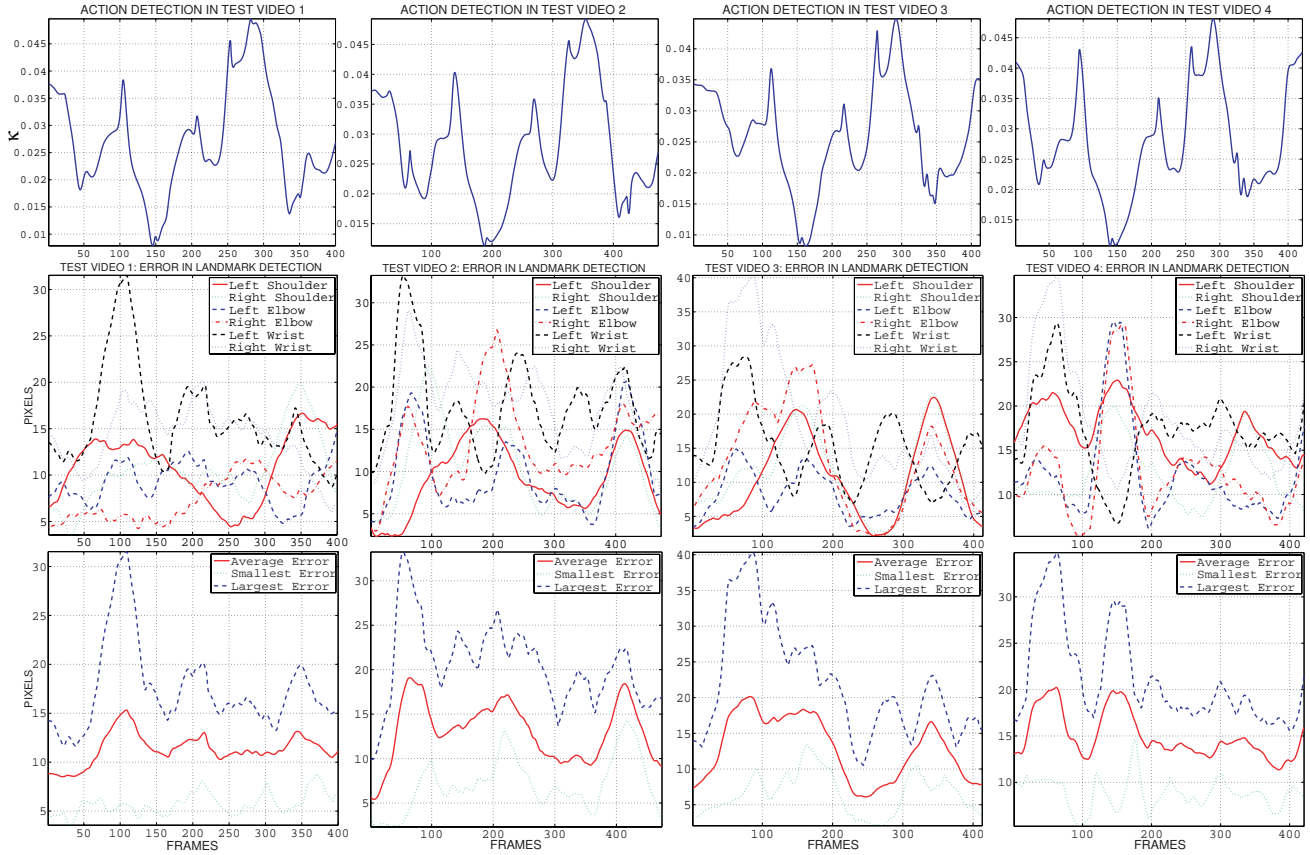

Fig. 10. The first row of the figure shows the results of detecting model action in the test video. The model action was detected around frame 150, 180, 160 and 150 of the test video 1, 2, 3 and 4, respectively. The second row shows the euclidian error of detecting landmarks on the left and right shoulders, elbows and wrists in each frame of the test video. The third row shows the minimal, average and maximal euclidian error of detecting all 13 landmarks in each frame of the test video.

was summed up and averaged over 50 frames. The second row of Figure 10 shows the average detection error of the landmarks selected on the left and right shoulders, elbows and wrists. The third row of Figure 10 shows the detection error averaged over 13 detected landmarks, smallest and largest detection error in each clip among 13 landmarks. In the presence of significant error in landmark detection in each frame and successful correct action detection, we see that proposed method is indeed robust to noise introduced by real body tracking algorithms.

### C. Quantitative Results

The following experiments quantitatively demonstrate that the proposed method is stable to changes in viewpoint, anthropometry and temporal behavior. A set of experiments were

performed to evaluate each of these three properties in isolation, followed by experiments evaluating performance under all three transformations simultaneously. Motion capture data was used to provide 3D data which was projected and used in all experiments. Since the 3D coordinates of the points were known, 2D image coordinates were obtained by generating projection matrices around a viewing sphere as shown in Figure 5. In all the experiments, actions were observed from 360 different locations in upper hemisphere, which means the elevation and azimuth were changed from 0 to 90 and from 0 to 350 degrees respectively at ten degree increments. Thus, a pair of angles, elevation and azimuth, corresponds to any of 360 possible camera locations<sup>2</sup>.

*1) Viewpoint:* In this experiment we tested the performance of the system with respect to changes in viewpoint. We demonstrated that the dissimilarity measure allows sufficient discrimination between matches and mismatches, despite different viewpoints. The first row of Figure 1 shows the input point cloud, representing the ‘getting up’ action, under different view projective transformations. The experimental performance is also tested with respect to increasing noise in the measurements.

We first experimented with noiseless data obtained through motion capture equipment and rendered data at regular intervals over the described viewing sphere. To demonstrate the robustness to changes in viewpoint we recorded the log of the condition number of  $\mathcal{A}_T$  and the log of the ratio of the second smallest singular value to the largest singular value in Figure 11 (a). This figure shows that regardless of view angles the dissimilarity measure (left half of the matrix or first 360 values on the horizontal axis) is very close to zero and significantly lower than the ratio of the second smallest singular value to the largest singular value (right half of the matrix). From the illustration, one can notice that the diagonal elements are especially low. The diagonal entities correspond to the case when both camera views are exact the same.

Within this matrix, there are blocks of low values, the indices of both axes are between 325 and 360. These values correspond to the case when elevation angles of both cameras, facing to the ground, are 90 degrees, and is a special case. From our experiment, in this case the values of the two ratios are approximately  $4.3 \times 10^{-22}$  and  $1.3 \times 10^{-20}$ , while in all other matches the

<sup>2</sup>The elevation and azimuth corresponding to some camera location  $n$ , where  $n = 1, \dots, 360$ , was calculated as  $\text{floor}((n - 1)/36) \times 10$  and  $\text{mod}((n - 1)/36) \times 10$  respectively, e.g., if  $n = 239$ , then the elevation and azimuth are 60 and 220 degrees respectively.

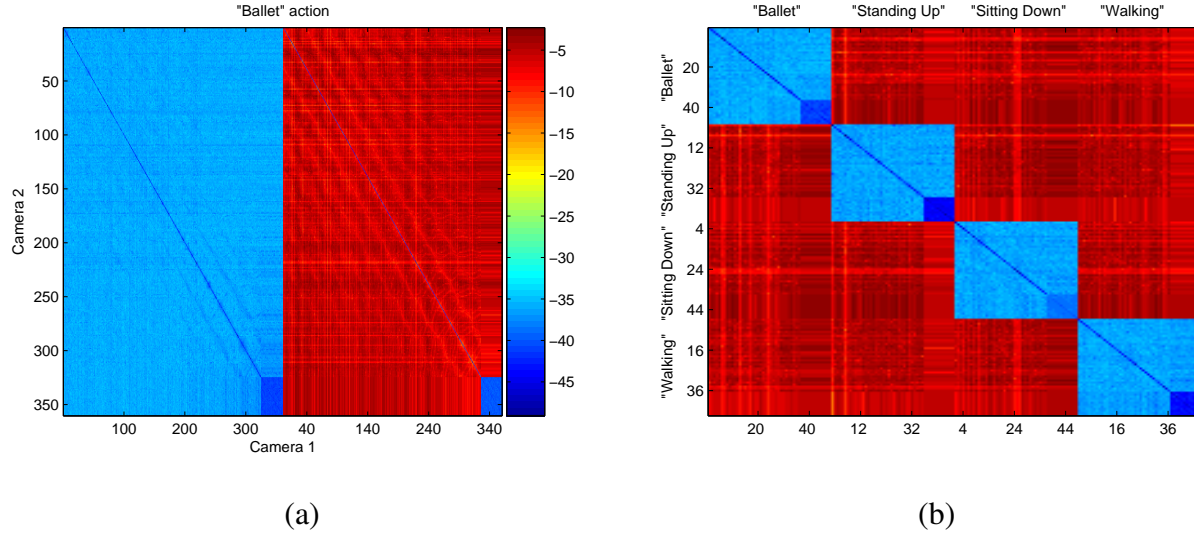

Fig. 11. Four different actions were compared to itself. The pattern (exemplar) and test actions were observed from any angle of the upper hemisphere. The left-most figure shows a significant drop between two ratios  $\sigma_9/\sigma_1$  (blue) and  $\sigma_8/\sigma_1$  (red), thus  $\sigma_9/\sigma_1$  can be considered as a dissimilarity measure. There are small rectangle areas of very low values corresponding to both ratios and lying between 325 and 350 indices. It occurs when both cameras has the elevation angle of 90 degrees, which corresponds to the upper point of hemisphere. Since at the upper point of hemisphere camera centers coincide, it becomes a degenerate case. The right-most figure shows the change of  $\sigma_9/\sigma_1$ , when under different view-projective transformations, four different actions were compared to each other. The low diagonal values of the proposed dissimilarity measure demonstrate the correct discrimination among actions.

mean of the dissimilarity measure is  $1.4 \times 10^{-16}$  and the mean of the other ratio is  $5.4 \times 10^{-4}$ .

Figure 11 (b) shows a confusion matrix using  $\log \kappa$  in a second series of experiments, where different actions were compared to each other. Four actions ('ballet', 'standing up', 'sitting down' and 'walking') were rendered from 360 different viewpoints and the block diagonal structure of the confusion matrix shows the discrimination achieved using the proposed measure. It is important to note that even in the special case mentioned above  $\kappa$  provides ample discrimination between different actions.

On these four actions, 'ballet', 'standing up', 'sitting down' and 'walking', we also tested the sensitivity of the metric with respect to noise and its behavior with respect to an increase in number of frames. The experimental results are presented in Figure 12. The pattern actions were all observed from a fixed viewpoint - the azimuth and elevation were 30 and 25 degrees respectively. The test actions were observed from a significantly distinct view angle, the azimuth

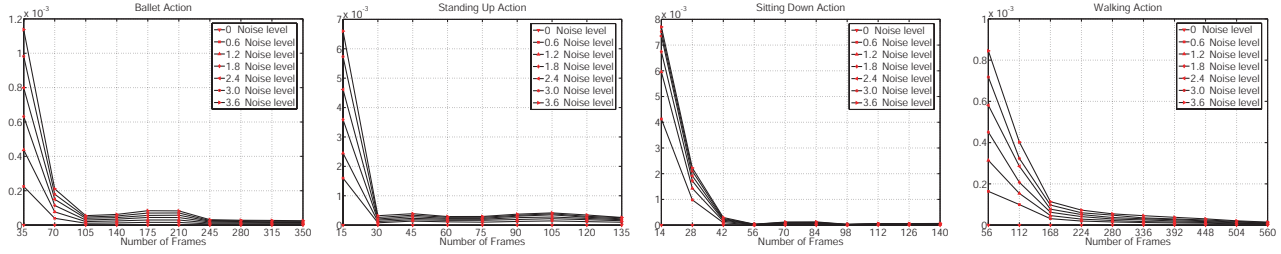

Fig. 12. The measure is robust to changes in viewpoint (different markers differentiate the different noise levels). This figure shows how the proposed dissimilarity measure changes with respect to the level of noise and the view angle. Patterns of four actions were captured at the same view point, azimuth= 30 and elevation= 25 degrees, and test actions were observed by the stationary camera at view point corresponding to the azimuth= 130 and elevation= 45 degrees. Six levels of noise, sampled from zero mean normal distribution with  $\sigma$  varying from 0.6 to 3.6, were added to the 2D image coordinates. Regardless of the action, when the length of the action increases, the dissimilarity measure approaches zero. The  $X$ -axis shows the number of frames, and the  $Y$ -axis shows the values of  $\kappa$ .

and elevation were 130 and 45 degrees respectively. Six levels of noise, sampled from a zero-mean normal distribution with  $\sigma$  varying from 0.6 to 3.6, were added to the test actions. Twenty five samples were generated from at each noise strength and the mean error at each noise level was recorded. As expected estimates of  $\kappa$  become more reliable as the number of frames increases, and the number of frames after which  $\kappa$  is stable, varies from action to action, depending largely on the ‘content’ of the action.

2) *Anthropometry*: In this experiment we examined the performance of  $\kappa$  with respect to change in the anthropometry of the actor. The second row of the Figure 1 shows the ‘getting up’ action under different anthropometric transformations. Figure 13 presents the experimental results. The pattern action was observed from a view point with a fixed elevation of 60 degrees, while the azimuth was changed from 0 to 350 degrees. Similarly, the test action was observed from a view point with a fixed elevation of 30 degrees, while the azimuth was changed from 0 to 350 degrees. A  $4 \times 4$  matrix  $\mathcal{M}$  was randomly generated, and the whole action was transformed by  $\mathcal{M}$ . After 3D projective transformation, 3D points were projected onto image plane and distorted by six different levels of noise. Noise parameters were the same as in the previous set of experiments. The results showed  $\kappa$  to be robust to noise, and estimates of  $\kappa$  became more reliable as the number of frames were increased. As in the previous experiment, the number of frames after which  $\kappa$  stabilized, varied from action to action and depended on the action.

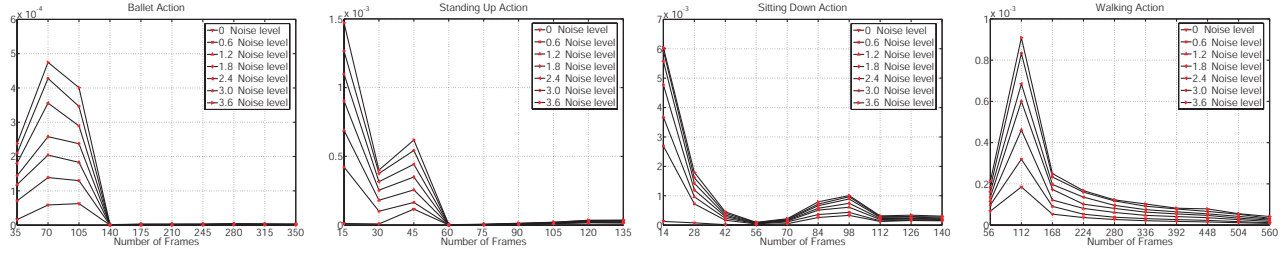

Fig. 13. Stability with respect to anthropometric transformation. The figure shows how  $\kappa$  changes with respect to the level of noise and the length of the action. Exemplars of four actions were captured at the same view point, azimuth= 30 and elevation= 25 degrees, and test actions were observed by the moving camera at the different view point, azimuth= 130 and elevation= 25 degrees. Six different levels of noise, sampled from a zero-mean normal distribution with  $\sigma$  varying from 0.6 to 3.6, were added to the 2D image coordinates. Regardless of the action, when the length of the action increases, the dissimilarity measure approaches zero.

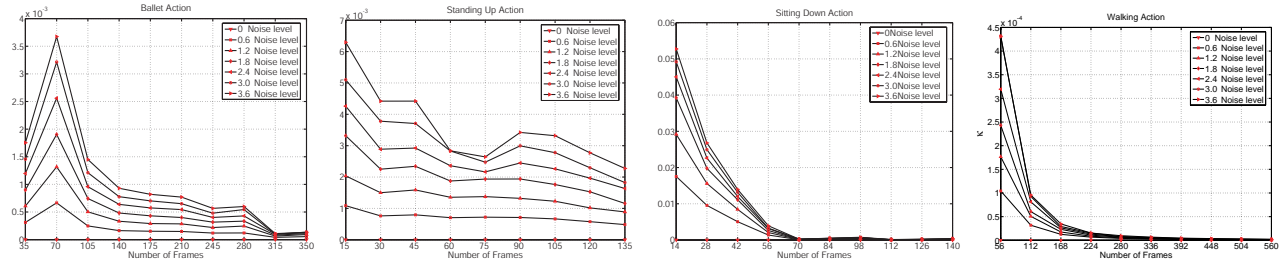

Fig. 14. The proposed dissimilarity measure is stable to temporal distortion. The figure shows how the proposed dissimilarity measure changes with respect to the level of noise and the length of the action. Patterns of four actions were captured at the same view point, azimuth= 30 and elevation= 25 degrees, and test actions were observed by the moving camera at the different view point, azimuth= 130 and elevation= 25 degrees. Six different levels of noise, sampled from a zero-mean normal distribution with  $\sigma$  varying from 0.6 to 3.6, were added to the 2D image coordinates. Regardless of the action, when the length of the action increases, the dissimilarity measure is approaching to zero.

3) *Execution Rate*: This set of experiments demonstrates the robustness to temporal transformation of actions. Figure 14 shows the results. Exemplars of four actions were observed from a constant viewpoint - the azimuth and elevation were 30 and 25 degrees respectively. Test actions were observed at different view angle corresponding to the azimuth 130 and elevation 45 degrees. The test actions were distorted temporally by generating a pair  $(a_1, a_2)$  and by the same six levels of noise specified earlier. Once again we note that the longer the greater the distinctive content the action the more robust the matching.

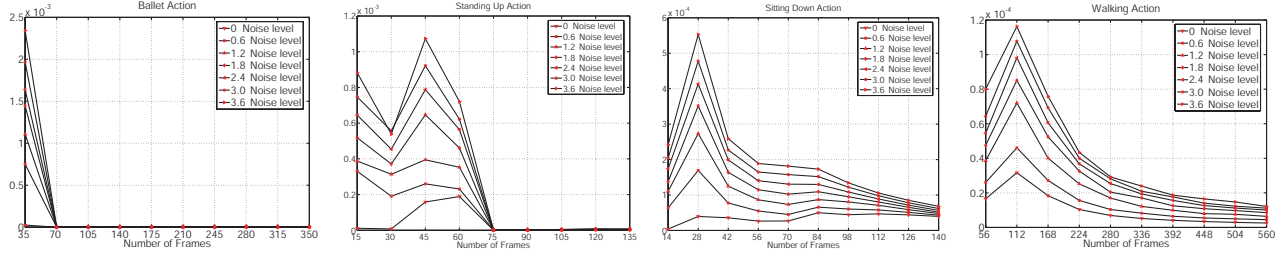

Fig. 15. The dissimilarity measure is robust to temporal, anthropometric and view distortion. This figure shows how the dissimilarity changes with respect to the level of noise and the length of the action. From left to right, four figures correspond to ‘ballet’, ‘standing up’, ‘sitting down’ and ‘walking actions’. Patterns of four actions were captured by the moving camera with a fixed orientation, azimuth= 30 and elevation= 45 degrees, and test actions were observed by the stationary camera at the view point with azimuth= 130 and elevation= 10 degrees. Six different levels of noise, sampled from the normal distribution with means from 0.6 to 3.6 and  $\sigma = 1$ , were added to the 2D image coordinates. When the length of the action increases, the dissimilarity approaches zero. The  $X$ -axis shows the number of frames, and the  $Y$ -axis shows the values of  $\kappa$ .

4) *Simultaneous Distortion of Temporal Index, Viewpoint and Anthropometry*: The last series of experiments was performed both on rendered motion capture data and real imaged data. In these experiments we aimed to analyze the performance of  $\kappa$  for application in action recognition.

The first set of experiments performed on the synthetic data. The results presented in Figure 15 demonstrate the behavior of the dissimilarity measure,  $\kappa$ , with respect to all three types of transformations. Exemplars of the four actions (‘ballet’, ‘standing up’, ‘sitting down’ and ‘walking’) were captured by a virtual camera moving at constant velocity but a fixed orientation, azimuth= 30 and elevation= 45 degrees. Test actions were captured by the virtual stationary camera at the view point with azimuth= 130 and elevation= 10 degrees. Similar to the previous experiments, six different levels of noise sampled from the normal distribution with means from 0.6 to 3.6 and  $\sigma = 1$  were added to the image coordinates. All results show robustness of  $\kappa$  with respect to noise.

The second set of experiments was performed on trajectories generated by the walking action. One cycle of the walking action, performed by Actor 1, was a pattern action and was captured outdoors by a stationary camera. The model action was 42 frames long. It is important to note that during the action, the pose of the actor was changing relative to the camera position. Since we consider points on the actor’s body only, the stationary camera can be interpreted as a *moving* camera, and moving actor can be considered stationary. The first test clip (570

frames) was chosen from a motion capture data set. We synthesized a camera, virtually moving in 3D, and projected original data on the image plane of that camera. The second and third clips depicted Actors 2 and 3 performing "walking action" on a treadmill, and the fourth clip depicted the Actor 3 performing "bicycling action" on a recumbent bicycle. The test actions, two walking and bicycling actions, were 374, 202 and 212 frames, respectively. The goal of the experiments was to determine whether the query actions, captured by moving and stationary cameras, contain the pattern action, captured by stationary camera. The results are presented in Figure 16. The leftmost image of the first row shows Actor 1 performing the pattern action. The remain three images of the first row correspond to the query actions performed by Actors 2 and 3, respectively. The second row shows the variation of  $\kappa$  as the pattern action was shifted in time over the duration of the test actions. The left-most figure shows the result of pattern detection in the clip from Motion capture data set, and other three figures show the results of pattern detection in second, third and fourth clips, respectively. The rightmost figure shows results of a video that did not contain any walking actions. Since that video depicted the bicycling action, we do observe some periodicity. However, the values corresponded to each potential action occurrences (local minima) were greater than values corresponded to action occurrences in video depicted walking action (see central figures).

While the above experiments determined only the location of action in test video (time translation), the final set of experiments determined the scale of temporal transformation. From all action occurrences in the previous experiment, only one occurrence was chosen in each video. Figure 17 demonstrates the results. The leftmost figure from the top row shows the result obtained on synthetic video. The best match was detected when the scale of temporal transformation was one, and this coincides with the ground truth. The other two figures from the top row show the results obtained on real video. Compared to the model action, in both test videos, actors were walking slightly faster, which was captured by the scale factor. In order to get the best match, actions from the test video were scaled to match the model action. Analyzing results from both synthetic and real video, it is easy to see that the global minima in the left-most figure is more distinct when compared to the other two. This is attributed to noise, the length of the model action and our assumption, which is that we know the beginning point of action and do not know where action ends. As soon as a test fragment contains the action,  $\kappa$  becomes less sensitive to increase in scale. This effect is still observable in synthetic video but to a lesser

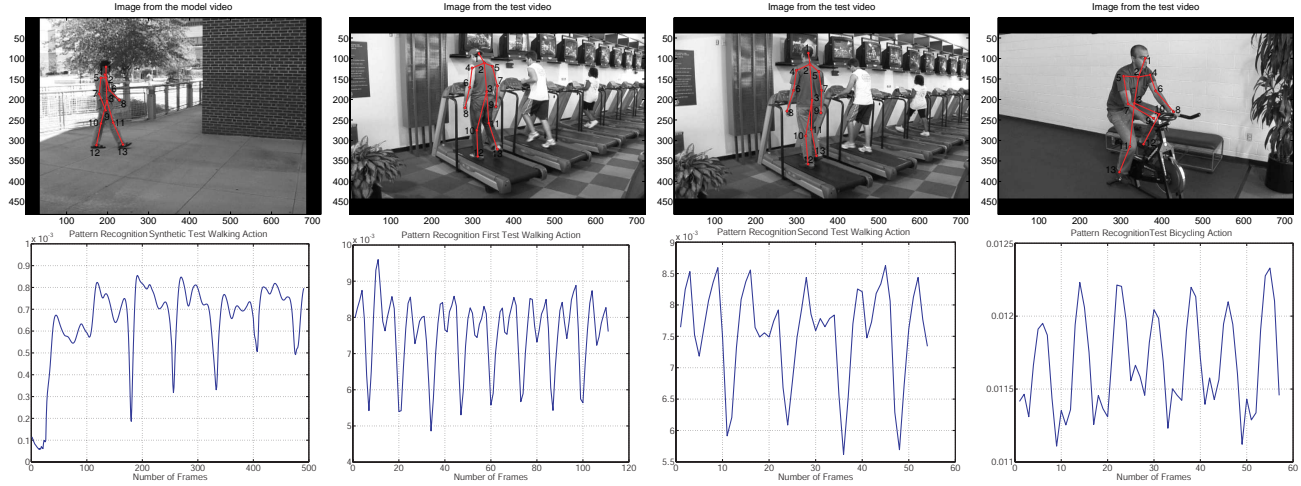

Fig. 16. The first row shows images from real video. The left-most image corresponds to the model action, and the remaining three correspond to the test actions. The second row shows results of pattern detection. The left-most figure corresponds to recognition in synthetic video. The length of the model and test video was 70 and 564 frames respectively. Two central figures shows detection of walking in real video containing walking actions. The model, and two test video were 42, 374 and 202 frames respectively. In model and test video points on bodies were marked in each third frame. The right-most figure shows the result of detection of walking action in real video that did not contain any walking actions. The test video was 212 frames long. The values of local minima in the right-most figure are greater than ones in two central figures.

degree. The remaining three rows show the corresponding frames after synchronization between model action and test fragments.

## VIII. CONCLUSION

In this paper we have addressed the analysis of trajectories of anatomical landmarks in the presence of three key sources of distortion: viewpoint of observation, anthropometric proportion of actors, and differing rates of execution. We demonstrate, first theoretically and then empirically, that the algorithm based on the proposed dissimilarity measure is stable with respect to changes in all three distortions. During experimentation, we examine each source of distortion in isolation, followed by an evaluation in the presence of simultaneous distortion and report the quantitative performance. In addition, we provide several qualitative examples demonstrating the applicability of the proposed approach. We show various applications of proposed approach, such as video synchronization, computer aided training, and human action recognition.

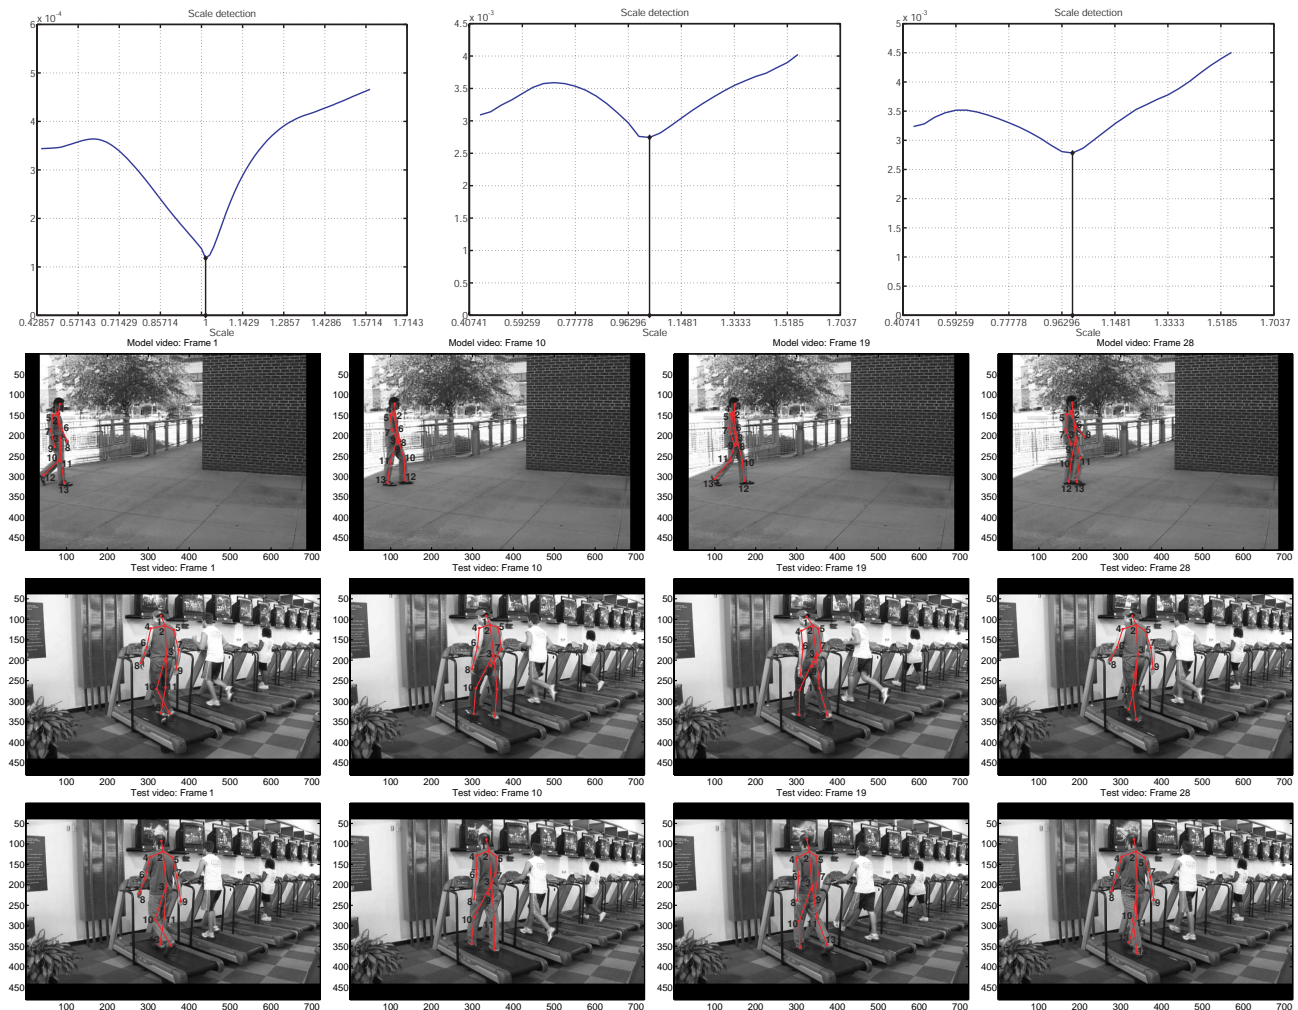

Fig. 17. The top row shows the results of temporal scale detection. The left-most figure shows the result of detection in synthetic video. The best match corresponds to the point where the scale is one. The remain two figures show results of scale detection in real video. Since both actors were walking faster than in the model, the best matchings correspond to the scales, which are slightly greater than one. The remaining rows show the corresponding frames after synchronization. The second-top row shows frames from the model video, and others show frames from the test video.
