Part I

Behavioural Specifications
Chapter 1

Conventions

For concision, the specifications in this document are typically phrased as implications so that they only apply to expressions that terminate. It is not the case that all expressions terminate. If a higher order function is applied to arguments including a function and input for that function on which it does not terminate, then the application will likely not terminate.

The specifications in this document often contain data type definitions and code fragments in SML-like syntax. These fragments exist to clearly and carefully specify the behaviour of the value being documented, not to restrict its possible implementations. Structures do not need to implement the signature with exactly these code fragments; they are typically extremely inefficient. They also contain a mixture of SML syntax and notation from the abstractions in play, and therefore do not immediately compile.

Two functions $f$ and $g$ are said to be logically equivalent if they give equal results on equal arguments. It follows that if $f$ is logically equivalent to $g$, and $f$ does not terminate on some input, then $g$ does not terminate on that input.

We use math and monospace fonts to indicate the difference between the abstraction implemented by an abstract type and SML representations of that abstract notion, respectively. If the same letter or identifier appears in both fonts, it should be understood to mean either the abstraction or representation of the same object.

Types are always typeset in a math font for readability, corresponding to the typical pronunciation of concrete SML syntax. For example, the type of a function

$$f : 'a \to ('a \times 'b) \to 'c$$

will be written

$$f : \alpha \to \alpha \times \beta \to \gamma$$

When talking about a polymorphic expressions in prose, we will often omit the type variable that they are polymorphic over. For example, we may say that “$i$ is a list” to mean “$i$ has type $\alpha \text{ list}$”.

The specifications often use the phrase “$x$ is a $t$ value”, where $t$ is some type. For example, when we say “$i$ is an int value” we mean that $i$ is an expression with type $\text{int}$ that cannot be evaluated further, like 7 but not like $((\text{fn } x \Rightarrow x) \ 7)$.

Combining combing the above two conventions, the statement

“$s$ is a sequence value”

should be taken to mean

“$s$ has type $\alpha \ \text{seq}$, and $s$ is a value”

or, more specifically,

“$s$ has type $\alpha \ \text{seq}$, and for every valid index $i$ into $s$, $s_i$ is a value”
Chapter 2

PRIORITY_QUEUE Signature

2.1 Overview

2.1.1 Priority Queues

The priority queue abstract data type is a multiset of key-value pairs, where the keys belong to a total ordering. The operations are constrained so that relatively simple data structures can be used to implement them. Since it is treated as a multiset, insertion will always increase the size by one, and deleting the minimum value will decrease the size by one unless the queue is empty.

2.2 Signature Definition

signature PRIORITY_QUEUE =
  sig
    structure Key : ORDERED
    type key = Key.t
    type 'a pq
    type 'a t = 'a pq
    val empty : unit -> 'a pq
    val isEmpty : 'a pq -> bool
    val singleton : key * 'a -> 'a pq
    val insert : (key*'a) -> 'a pq -> 'a pq
    val meld : 'a pq -> 'a pq -> 'a pq
    val findMin : 'a pq -> (key*'a) option
    val deleteMin : 'a pq -> (key*'a) option * 'a pq
  end

2.3 Details of Types

2.3.1 key

This indicates that the type of keys in a priority queue has to have type key.

2.3.2 αpq

This is the abstract type representing a priority queue with key type key (see below) and value type α.
2.4 Details of Values

2.4.1 empty: \( \text{unit} \rightarrow \alpha pq \)

empty represents the empty collection \( \emptyset \).

2.4.2 isEmpty: \( \alpha pq \rightarrow \text{bool} \)

Returns true if the priority queue is empty.

2.4.3 singleton: \( \text{key} \times \alpha \rightarrow \alpha pq \)

If \( k \) is a value of type \( \text{key} \) and \( v \) is a value of type \( \alpha \), the expression \( \text{singleton} \ (k,v) \) evaluates to the priority queue including just \( \{(k,v)\} \).

2.4.4 insert: \( (\text{key} \times \alpha) \rightarrow \alpha pq \rightarrow \alpha pq \)

For a key-value pair \( (k,v) \), and a priority queue \( Q \), \( \text{insert} \ (k, v) \ Q \) evaluates to \( Q \cup \{(k,v)\} \). Since the priority queue is treated as a multiset, duplicate keys or key-value pairs are allowed and kept separately.

2.4.5 meld: \( \alpha pq \rightarrow \alpha pq \rightarrow \alpha pq \)

Takes the union of two priority queues. Since the priority queue is treated as a multiset, duplicate keys or key-value pairs are allowed and kept. Therefore the size of the result will be the sum of the sizes of the inputs.

2.4.6 findMin: \( \alpha pq \rightarrow (\text{key} \times \alpha) \ \text{option} \)

Given a priority queue \( \text{findMin} \ Q \) if \( Q \) is empty, it returns NONE. Otherwise it returns \( \text{SOME}(k,v) \) where \( (k,v) \in Q \) and \( k \) is the key of minimum value in \( Q \). If multiple elements have the same minimum valued key, then an arbitrary one is returned.

2.4.7 deleteMin: \( \alpha pq \rightarrow (\text{key} \times \alpha) \ \text{option} \times \alpha pq \)

This is the same as \( \text{findMin} \) but also returns a priority queue with the returned (key,value) pair removed (if the input queue is non-empty) or an empty \( Q \) (if the input queue is empty).
Chapter 3

SEQUENCE Signature

3.1 Overview

3.1.1 Abstract Sequences

We define an abstract mathematical notion of a sequence. The documentation for the signature that follows states the behaviour of implementations in terms of this abstraction.

- A sequence is an ordered finite list of elements of some type, indexed by the natural numbers.
- The length of a sequence is the number of elements in that sequence. If $s$ is a sequence, its length is denoted $|s|$.
- A natural number $i$ is said to be a valid index into the sequence $s$ if and only if $0 \leq i < |s|$.
- If $s$ is any sequence and $i$ is a valid index into $s$, then $s_i$ denotes the $i^{th}$ element of $s$.
- If $s$ is a particular sequence with $n$ elements, we may denote $s$ with the notation $\langle s_0, s_1, \ldots, s_{n-1} \rangle$.

For example,

\[
\langle \rangle
\]

denotes the empty sequence and

\[
\langle 4, 2, 3 \rangle
\]

denotes a particular sequence of natural numbers with length three.

- A sequence $s'$ is said to be a subsequence of a sequence $s$ if there is a strictly increasing, possibly empty, sequence $I$ of valid indices into $s$ such that $s'_i = s_{I_i}$.
- Sequences can only be ordered if their elements can be ordered. If that condition is met, sequences are ordered lexicographically.

3.2 Signature Definition

```plaintext
signature SEQUENCE =
  sig
  type 'a seq
```
Figure 3.1: Reduce tree structure for any sequence $s$ with $|s| = 7$

datatype 'a treeview = EMPTY
  | ELT of 'a
  | NODE of ('a seq * 'a seq)

val % : 'a list -> 'a seq
end

3.3 Details of Types

3.3.1 $\alpha$ seq

This is the abstract type that represents the notion of a sequence described in section 3.1.1.

3.3.2 $\alpha$ treeview

$\alpha$ treeview provides a view of the abstract $\alpha$ seq type as a binary tree.

3.3.3 $\alpha$ listview

$\alpha$ listview provides a view of the abstract $\alpha$ seq type as a list.

3.3.4 $\alpha$ ord

The type $\alpha$ ord represents an ordering on the type $\alpha$ as a function from pairs of elements of $\alpha$ to order.

3.4 Details of Exceptions

3.4.1 Range

Range is raised whenever an invalid index into a sequence is used. The specifications for the individual functions state when this will happen more precisely.

This is the only exception that the functions in a module ascribing to SEQUENCE raise. An expression applying such a function to appropriate arguments may raise other exceptions, but it will do so only because one of the arguments in that application raised the other exception.

3.5 Details of Values

3.5.1 empty: unit $\rightarrow$ $\alpha$ seq

(empty ()) evaluates to ()

3.5.2 singleton: $\alpha$ $\rightarrow$ $\alpha$ seq

If x is a value, then (singleton x) evaluates to (x).
3.5.3 length: \(\alpha \text{ seq} \rightarrow \text{int}\)
If \(s\) is a sequence value, then \((\text{length } s)\) evaluates to \(|s|\).

3.5.4 nth: \(\alpha \text{ seq} \rightarrow \text{int} \rightarrow \alpha\)
If \(s\) is a sequence value and \(i\) is an \(\text{int}\) value and \(i\) is a valid index into \(s\), then \((\text{nth } s \ i)\) evaluates to \(s_i\).
This application raises \text{Range} if \(i\) is not a valid index.

3.5.5 tabulate: \((\text{int} \rightarrow \alpha) \rightarrow \text{int} \rightarrow \alpha \text{ seq}\)
If \(f\) is a function and \(n\) is an \(\text{int}\) value, then \((\text{tabulate } f \ n)\) evaluates to a sequence \(s\) such that \(|s| = n\) and, for all valid indicies \(i\) into \(s\), \(s_i\) is the result of evaluating \((f \ i)\).
Note that the evaluation of this application will only terminate if \(f\) terminates on all valid indices into the result sequence \(s\).

3.5.6 fromList: \(\alpha \text{ list} \rightarrow \alpha \text{ seq}\)
If \(l\) is a list value, then \((\text{fromList } l)\) evaluates to the index preserving sequence representation of \(l\). That is to say, \text{fromList} is logically equivalent to
\[
\text{fn } l \Rightarrow \text{tabulate (fn } i \Rightarrow \text{List.nth(l,i)}) \text{ (List.length l)}
\]

3.5.7 collate: \(\alpha \text{ ord} \rightarrow \alpha \text{ seq ord}\)
If \(\text{ord}\) is an ordering on the type \(\alpha\), \text{collate ord} evaluates to an ordering on the type \(\alpha \text{ seq}\) derived lexicographically from \(\text{ord}\).

3.5.8 map: \(\alpha \rightarrow \beta \rightarrow \alpha \text{ seq} \rightarrow \beta \text{ seq}\)
If \(f\) is a function and \(s\) is a sequence value such that \(|s| = n\), then \((\text{map } f \ s)\) evaluates to the sequence \(r\) such that \(|r| = n\) and, for all valid indicies \(i\) into \(s\), \(r_i\) is the result of evaluating \((f \ s_i)\).
Note that the evaluation of this application will only terminate if \(f\) terminates on \(s_i\) for all valid indicies \(i\).

3.5.9 map2: \(((\alpha \times \beta) \rightarrow \gamma) \rightarrow \alpha \text{ seq} \rightarrow \beta \text{ seq} \rightarrow \gamma \text{ seq}\)
If \(f\) is a function and \(s_1\) and \(s_2\) are sequence values, then \((\text{map2 } f \ s_1 \ s_2)\) evaluates to the sequence \(r\) such that \(r_i\) is the result of evaluating \(f (s_{1,i}, s_{2,i})\) for all \(i\) that are valid indices into both \(s_1\) and \(s_2\).
It follows from the definition of a valid index and the above specification that
\[
|r| = \min(|s_1|, |s_2|)
\]
Note that the evaluation of this application will only terminate if \(f\) terminates on \((s_{1,i}, s_{2,i})\) for all \(0 \leq i < |r|\).
3.5.10 reduce: \(((α × α) → α) → α → α\) \(seq → α\)

To define the behaviour of reduce, we’ll first define a type of non-empty binary trees, then a mapping from non-empty sequences to those trees, then an analog to reduce on trees, and finally reduce on sequences.

The type of non-empty trees we’ll use is

```haskell
datatype 'a tree = Leaf of 'a
    | Node of ('a tree * 'a tree)
```

Assume that prevpow2 is a function with type \(\text{int} → \text{int}\) such that if \(x\) is an \(\text{int}\) value then \(\text{prevpow2}\) \(x\) evaluates to the maximum element of the set

\[
\{ y | y < x ∧ ∃i ∈ \mathbb{N}. y = 2^i \}
\]

With these two assumptions, we define a mapping from non-empty sequences to trees as

```haskell
fun toTree s =
  case |s|
  of 1 => Leaf(s0)
    | n => Node(toTree (take (s, prevpow2 |s|)),
     toTree (drop (s, prevpow2 |s|)))
```

The result of this is a nearly-balanced tree where the number of leaves to the left of any internal node is the greatest power-of-two less than the total number of leaves below that node. The structure of such trees depends only on the length of the input sequence. An example tree is shown in Figure 3.1.

We’ll now define the function reducet for the tree type. reducet has type

\(((α × α) → α) → α\) \(tree → α\)

and is defined as

```haskell
fun reducet f (Leaf x) = x
    | reducet f (Node(l,r)) = f(reducet l, reducet r)
```

Finally, if \(f\) is a function, \(b\) a value, and \(s\) a sequence value, there are two cases:

- If \(|s| = 0\) then \((\text{reduce } f \ b \ s)\) evaluates to \(b\).
- If \(|s| > 0\), and \((\text{reducet } f \ (\text{toTree } s))\) evaluates to some value \(v\), then \((\text{reduce } f \ b \ s)\) evaluates to \(f(b, v)\).

Note that this definition does not require that \(f\) is associative. The transformation to trees and reduce on trees are both well-defined without respect to any associativity of \(f\). The tree structure defined by toTree defines a particular association of \(f\) on any sequence: if we use \(⊕\) as infix notation for \(f\), the tree corresponds to exactly one of the many ways to parenthesize the expression

\[ b ⊕ (s_0 ⊕ s_1 ⊕ ... ⊕ s_{|s|-1}) \]

If \(f\) happens to be associative, all of the possible ways to parenthesize this expression result in the same computation.

It follows that if \(f\) is associative and \(b\) is a value such that \(b\) is the identity of \(f\), reduce \(f\) \(b\) is logically equivalent to iter \(f\) \(b\).
3.5.11 argmax: $\alpha \ ord \rightarrow \alpha \ seq \rightarrow \ int$

If $S$ is a sequence of type $\alpha$ and $f$ defines a total ordering on the elements of type $\alpha$, then $\text{argmax } f \ S$ returns an index (location in the sequence) of a maximal value in $S$. Maximal is defined with respect to $f$. This function raises $\text{Range}$ if the $S$ is empty.

3.5.12 scan: $((\alpha \times \alpha) \rightarrow \alpha) \rightarrow \alpha \rightarrow \alpha \ seq \rightarrow (\alpha \ seq \times \alpha)$

If $f$ is an associative function, and $b$ a value such that $b$ is an identity of $f$, $(\text{scan } f \ b)$ is logically equivalent to

$$\text{fn } s \Rightarrow \left(\text{tabulate } (\text{fn } i \Rightarrow \text{reduce } b \ (\text{take}(s,i))) \ (\text{length } s), \ \text{reduce } f \ b \ s\right)$$

3.5.13 filter: $(\alpha \rightarrow \text{bool}) \rightarrow \alpha \ seq \rightarrow \alpha \ seq$

If $p$ is a predicate and $s$ is a sequence value, then $(\text{filter } p \ s)$ evaluates to the longest subsequence $s'$ of $s$ such that $p$ holds for every element of $s'$.

3.5.14 iter: $(\beta \times \alpha \rightarrow \beta) \rightarrow \beta \rightarrow \alpha \ seq \rightarrow \beta$

$\text{iter}$ is logically equivalent to $\text{iterate}$, defined below.

$$\text{fun iterate } f \ b \ s =$$
$$\text{case showl } s$$
$$\text{of } \text{NIL} \Rightarrow b$$
$$\mid \text{CONS } (x, xs) \Rightarrow \text{iter } f \ (f(b, x)) \ xs$$

Less formally, if $f$ is a function, $b$ is a value, and $s$ is a sequence value, then $(\text{iter } f \ b \ s)$ computes the iteration of $f$ on $s$ with left-association and $b$ as the base case. We can write this iteration as

$$f(f(...f(b, s_0), ..., s_{|s|-2}), s_{|s|-1})$$

or, using $\oplus$ as infix notation for $f$,

$$(...(((b \oplus s_0) \oplus s_1) \oplus s_2) \oplus ... s_{|s|-1})$$

3.5.15 iterh: $(\beta \times \alpha \rightarrow \beta) \rightarrow \beta \rightarrow \alpha \ seq \rightarrow (\beta \ seq \times \beta)$

$\text{iterh}$ is a generalization of $\text{iter}$ that also computes the sequence of all partial results produced by the iterated application of the functional argument. Specifically, $(\text{iterh } f \ b)$ is logically equivalent to

$$\text{fn } s \Rightarrow \left(\text{tabulate } (\text{fn } i \Rightarrow \text{iter } f \ b \ (\text{take}(i, s))) \ (|s|), \ \text{iter } f \ b \ s\right)$$

3.5.16 flatten: $\alpha \ seq \ seq \rightarrow \alpha \ seq$

$\text{flatten}$ is logically equivalent to $(\text{iter append } \ (\text{empty } ()))$.

Less formally, if $s$ is a sequence value of sequence values, then $(\text{flatten } s)$ evaluates to the concatenation of the sequences in $s$ in the order that they appear in $s$. 

13
3.5.17 partition: \( \text{int seq} \rightarrow \alpha \text{ seq} \rightarrow \alpha \text{ seq seq} \)

If \( I \) is an \( \text{int} \) sequence value and \( s \) is a sequence value, then \((\text{partition } I \ s)\) evalulates to a sequence of sequences \( p \) such that \(|p| = |I|\) and, for every \( i \) that’s a valid index of \( I \), \( p_i \) is a subsequence of \( s \) of length \( I_i \) starting at index

\[
\sum_{j=0}^{i-1} I_j
\]

in \( s \).

That is to say, \( \text{partition} \) produces a sequence of adjacent subsequence of \( s \) with lengths specified by the elements of \( I \).

Let

\[
l := \sum_i I_i
\]

\( \text{partition} \) has the property that for any sequence \( s \),

\[
(\text{flatten } (\text{partition } I \ s))
\]

is the first subsequence of \( s \) of length \( l \). In particular, if \( l = |s| \), this means that

\[
\text{fn ss} \Rightarrow (\text{partition } (\text{map length ss}) \ (\text{flatten ss}))
\]

is functionally equivalent to the identity function on \( \text{tseq}\alpha \text{ seq} \).

3.5.18 inject: \( (\text{int } \times \alpha) \text{ seq} \rightarrow \alpha \text{ seq} \rightarrow \alpha \text{ seq} \)

Let \( \text{ind} \) and \( s \) be sequence values and let

\[
\text{occ}(i) := \{ j | \text{ind}_j = (i, x) \text{ for some } x \}
\]

\((\text{inject } \text{ind} \ s)\) evaluates to the sequence \( s' \) with length \(|s|\), where for all valid indices \( i \) into \( s \)

\[
s'_i = \begin{cases} s_i & \text{occ}(i) = \{ \} \\ x & j = \text{max}(\text{occ}(i)) \land \text{ind}_j = (i, x) \end{cases}
\]

This application will raise \( \text{Range} \) if any element of \( \text{ind} \) has a first component that is not a valid index into \( s \).

3.5.19 append: \( \alpha \text{ seq } \times \text{ int} \rightarrow \alpha \text{ seq} \rightarrow \alpha \text{ seq} \)

If \( s_1 \) and \( s_2 \) are sequence values, then \((\text{append } (s_1, s_2))\) evaluates to a sequence \( s \) with length \(|s_1| + |s_2|\) such that the subsequence of \( s \) starting at index 0 with length \(|s_1|\) is \( s_1 \) and the subsequence of \( s \) starting at index \(|s_1|\) with length \(|s_2|\) is \( s_2 \).

3.5.20 take: \( \alpha \text{ seq } \times \text{ int} \rightarrow \alpha \text{ seq} \)

If \( s \) is a sequence value and \( n \) is an integer, then \((\text{take } (s, n))\) evaluates to the first subsequence of \( s \) of length \( n \). This application will raise \( \text{Range} \) if \( n > |s| \).

3.5.21 drop: \( \alpha \text{ seq } \times \text{ int} \rightarrow \alpha \text{ seq} \)

If \( s \) is a sequence value and \( n \) is an integer, then \((\text{drop } (s, n))\) evaluates to the last subsequence of \( s \) of length \(|s| - n \). This application will raise \( \text{Range} \) if \( n > |s| \).
3.5.22 subseq: $\alpha \text{ seq} \rightarrow (\text{int} \times \text{int}) \rightarrow \alpha \text{ seq}$

If $s$ is a sequence value and $j$ and $\text{len int}$ are values such that $j + \text{len} \leq |s|$, then $(\text{subseq } s \ (j, \text{len}))$ evaluates to the subsequence $s'$ of $s$ of length $\text{len}$ such that $s'_i = s_{i+j}$ for all $i < \text{len}$.

This application will raise Range if the subsequence specification is invalid.

3.5.23 splitMid: $\alpha \text{ seq} \times \text{int} \rightarrow (\alpha \text{ seq} \times \alpha \times \alpha \text{ seq}) \text{ option}$

Let $s$ be a sequence value and $i$ an int value.

- If $|s| = 0$, then $(\text{splitMid}(s,i))$ evaluates to NONE.
- If $|s| > 0$, $(\text{splitMid}(s,i))$ evaluates to (SOME $(1, s_l, r)$) where $l$ is the first subsequence of $s$ of length $i - 1$ and $r$ is the last subsequence of $s$ of length $|s| - 1 - i$.

This application will raise Range if $i > |s|$.

3.5.24 sort: $\alpha \text{ ord} \rightarrow \alpha \text{ seq} \rightarrow \alpha \text{ seq}$

If ord is an ordering and $s$ is a sequence, $(\text{sort ord } s)$ evaluates to a rearrangement of the elements of $s$ that is sorted with respect to ord.

3.5.25 merge: $\alpha \text{ ord} \rightarrow \alpha \text{ seq} \rightarrow \alpha \text{ seq} \rightarrow \alpha \text{ seq}$

3.5.26 collect: $\alpha \text{ ord} \rightarrow (\alpha \times \beta) \text{ seq} \rightarrow (\alpha \times \beta \text{ seq}) \text{ seq}$

Let ord be an ordering and $s$ be a sequence of pairs. $(\text{collect ord } s)$ evaluates to a sequence of sequences where each unique first coordinate of elements of $s$ is paired with the sequence of second coordinates of elements of $s$. The resultant sequence is sorted by the first coordinates, according to ord. The elements in the second coordinates appear in their original order in $s$.

For example, if

$s = \langle (5, "b"), (1, "a"), (1, "b"), (1, "b") \rangle$

and ord is the usual ordering on integers, then $(\text{collect ord } s)$ will evaluate to

$\langle (1, ("a", "b", "b")), (5, ("b")) \rangle$

3.5.27 toString: $(\alpha \rightarrow \text{string}) \rightarrow \alpha \text{ seq} \rightarrow \text{string}$

If $f$ is a function and $s$ is a sequence value, $(\text{toString } f \ s)$ evaluates to a string representation of $s$. This representation begins with "\langle", which is followed by the results of applying $f$ to each element of $s$, in left-to-right order, interleaved with ",", and ends with "\rangle".

3.5.28 tokens: $(\text{char} \rightarrow \text{bool}) \rightarrow \text{string} \rightarrow \text{string seq}$

Let $p$ be a predicate on characters. A token is a non-empty maximal substring of a string not containing any character that satisfies $p$. If $p$ is a predicate on characters and $s$ is a string, $(\text{tokens } p \ s)$ evaluates to the sequence of tokens of $s$ in left to right order.

For example, tokens Char.isPunct " the, , horse" evaluates to

$\langle "the", "horse" \rangle$

and tokens Char.isPunct " the, horse" evaluates to

$\langle "the", "horse" \rangle$
3.5.29 **fields**: \((\text{char} \rightarrow \text{bool}) \rightarrow \text{string} \rightarrow \text{string seq}\)

Let \(p\) be a predicate on characters. A field is a possibly empty maximal substring of not containing any character that satisfies \(p\). If \(p\) is a predicate on characters and \(s\) is a string, \((\text{fields } p \ s)\) evaluates to the sequence of tokens of \(s\) in left to right order.

For example, \(\text{fields } \text{Char.isPunct} \ ''\text{the,},\text{,horse}''\) evaluates to \(\langle ''\text{the},'', ''\text{,horse}'' \rangle\)

and \(\text{fields } \text{Char.isPunct} \ ''\text{the,},\text{horse}''\) evaluates to \(\langle ''\text{the},'', ''\text{horse}'' \rangle\).

3.5.30 **showt**: \(\alpha \text{ seq} \rightarrow \alpha \text{ treeview}\)

Let \(s\) be a sequence value.

- If \(|s| = 0\), \((\text{showt } s)\) evaluates to \(\text{EMPTY}\).
- If \(|s| = 1\), \((\text{showt } s)\) evaluates to \(\text{ELT}(s_0)\).
- If \(|s| > 1\), and \(\text{NODE}(\text{take } (s, (|s|/2)), \text{drop } (s, (|s|/2)))\) evaluates to some value \(v\), \((\text{showt } s)\) evaluates to \(v\).

3.5.31 **showti**: \(\alpha \text{ seq} \rightarrow (\text{int} \rightarrow \text{int}) \rightarrow \alpha \text{ treeview}\)

Let \(s\) be a sequence value.

- If \(|s| = 0\), \((\text{showti } s \ f)\) evaluates to \(\text{EMPTY}\).
- If \(|s| = 1\), \((\text{showti } s \ f)\) evaluates to \(\text{ELT}(s_0)\).
- If \(|s| > 1\), \(f : \text{int} \rightarrow \text{int}\) is a function, and \(\text{NODE}(\text{take } (s, f \ |s|), \text{drop } (s, f \ |s|))\) evaluates to some value \(v\), \((\text{showti } s \ f)\) evaluates to \(v\).

3.5.32 **hidet**: \(\alpha \text{ treeview} \rightarrow \alpha \text{ seq}\)

Let \(tv\) be a \text{treeview} value.

- If \(tv\) is \(\text{EMPTY}\), then \((\text{hidet } tv)\) evaluates to \(\langle \rangle\).
- If \(tv\) is \((\text{ELT } x)\), then \((\text{hidet } tv)\) evaluates to \(\langle x \rangle\).
- If \(tv\) is \((\text{NODE } l, r)\), then \((\text{hidet } tv)\) evaluates to the same value as \(\text{append } (l, r)\).

3.5.33 **showl**: \(\alpha \text{ seq} \rightarrow \alpha \text{ listview}\)

Let \(s\) be a sequence value.

- If \(|s| = 0\), \((\text{showl } s)\) evaluates to \(\text{NIL}\).
- If \(|s| > 0\), \((\text{showl } s)\) evaluates to \(\text{CONS}(s_0, (s_1, \ldots, s_{|s|-1}))\).
3.5.34  **hidel**: $\alpha$ listview $\rightarrow$ $\alpha$ seq

Let lv be a listview value.

- If lv is NIL, then (hidel lv) evaluates to $\langle\rangle$.
- If lv is CONS(x, xs), then hidel lv evaluates to a sequence with length $|xs| + 1$ such that $s'_0$ is $x$ and $s'_i$ is $xs_i$ for all valid indices $i$ into $xs$. 
Chapter 4

SET Signature

4.1 Overview

We begin by describing an abstract notion of a set representation, which extends the standard mathematical sets. The documentation for the signature that follows states the behavior of implementations in terms of this abstraction.

Like a mathematical set, a set $S$ is a finite collection of unique elements of some type and the size of $S$, denoted by $|S|$, is the number of elements in that set. The crucial difference between a set in the mathematical sense and a set in this library is that a set here is always ordered: for enumeration purposes, the implementation gives an implicit ordering of the elements. The empty set, denoted by $\emptyset$, is a special set that represents an empty collection, so $|\emptyset| = 0$.

4.2 Signature Definition

```ml
signature SET =
sig
  type set
  type key
  type t = set
  structure Seq : SEQUENCE
  val empty : set
  val singleton : key -> set
  val size : set -> int
  val equal : set * set -> bool
  val iter : (’b * key -> ’b) -> ’b -> set -> ’b
  val filter : (key -> bool) -> set -> set
  val find : set -> key -> bool
  val union : (set * set) -> set
  val intersection : (set * set) -> set
  val difference : (set * set) -> set
  val insert : key -> set -> set
  val delete : key -> set -> set
  val fromSeq : key Seq.seq -> set
  val toSeq : set -> key Seq.seq
  val toString : set -> string
end
```
4.3 Details of Types

4.3.1 set
This is the abstract type representing a set described in Section 4.1.

4.3.2 key
This indicates that each element of a set has to have type key.

4.4 Details of Values

4.4.1 empty: set
empty represents the empty set \(\emptyset\).

4.4.2 singleton: key \rightarrow set
For a value \(x\) of type key, the expression singleton \(x\) evaluates to a set containing exactly \(x\).

4.4.3 size: set \rightarrow int
If \(s\) is a value of type set, then size \(s\) evaluates to \(|s|\) (i.e., the number of elements in the set represented by \(s\)).

4.4.4 equal: set \times set \rightarrow bool
If \(s1\) and \(s2\) are values of type set, then equal \((s1,s2)\) evaluates to true if \(s1\) and \(s2\) are identical sets (i.e, they have the exact same set of elements); otherwise, it evaluates to false.

4.4.5 iter: (\(\beta \times key \rightarrow \beta\)) \rightarrow \beta \rightarrow set \rightarrow \beta
If \(f\) is a function, \(b\) is a value, and \(s\) is a set value, then iter \(f\ b\ s\) iterates \(f\) with left association on \(s\) on an implementation-specified ordering, using \(b\) as the base case. That is to say, iter \(f\ b\ s\) evaluates to
\[
f(f(...f(b,s_{|s|-1})\ldots s_1),s_0),
\]
where \(s_0,s_1,\ldots,s_{|s|-1}\) are the elements of \(s\) listed in the order that the implementation chooses.

4.4.6 filter: (key \rightarrow bool) \rightarrow set \rightarrow set
If \(p\) is a predicate and \(s\) is a set value, then filter \(p\ s\) evaluates to the subset \(s'\) of \(s\) such that an element \(x \in s'\) if and only if \(p\) holds on \(x\).

4.4.7 find: set \rightarrow key \rightarrow bool
If \(s\) is a set value and \(k\) is a key value, then find \(s\ k\) evaluates to a boolean value indicating whether or not \(k\) is a member of \(s\).

4.4.8 union: (set \times set) \rightarrow set
If \(s\) and \(t\) are set values, union \((s,t)\) evaluates to the set \(s \cup t\).
4.4.9 intersection: \((set \times set) \rightarrow set\)
If \(s\) and \(t\) are set values, \(\text{intersection}(s, t)\) evaluates to the set \(s \cap t\).

4.4.10 difference: \((set \times set) \rightarrow set\)
If \(s\) and \(t\) are set values, \(\text{difference}(s, t)\) evaluates to the set \(s \setminus t\) (i.e. the set \(\{x \in s : s \not\in t\}\)).

4.4.11 insert: \(key \rightarrow set \rightarrow set\)
If \(k\) is a key value and \(s\) is a set, \(\text{insert}(k, s)\) evaluates to the set \(s \cup \{k\}\).

4.4.12 delete: \(key \rightarrow set \rightarrow set\)
If \(k\) is a key value and \(s\) is a set, \(\text{delete}(k, s)\) evaluates to the set \(s \setminus \{k\}\).

4.4.13 fromSeq: \(key\text{Seq. seq} \rightarrow set\)
If \(s\) is a sequence value of type \(key\text{ Seq.seq}\), then \(\text{fromSeq}(s)\) evaluates to the set containing the elements \(s_0, s_1, \ldots, s_{|s|-1}\). The ordering in the set representation may differ from the ordering in the sequence representation.

4.4.14 toSeq: \(set \rightarrow key\text{Seq. seq}\)
If \(s\) is a set value where the elements have type \(key\), then \(\text{toSeq}(s)\) evaluates to the sequence of type \(key\text{ Seq.seq}\) containing all \(|s|\) elements of \(s\) appearing in the order of the implementation’s choosing.

4.4.15 toString: \(set \rightarrow string\)
If \(s\) is a set, \(\text{toString}(s)\) evaluates to a string representation of \(s\) listing the elements of \(s\), interleaved with “, “.
Chapter 5

ST_SEQUENCE Signature

5.1 Overview

5.1.1 Abstract Sequences

We define an abstract mathematical notion of a sequence. The documentation for the signature that follows states the behaviour of implementations in terms of this abstraction.

- A sequence is an ordered finite list of elements of some type, indexed by the natural numbers.
- The length of a sequence is the number of elements in that sequence. If \( s \) is a sequence, its length is denoted \( |s| \).
- A natural number \( i \) is said to be a valid index into the sequence \( s \) if and only if \( 0 \leq i < |s| \).
- If \( s \) is any sequence and \( i \) is a valid index into \( s \), then \( s_i \) denotes the \( i^{th} \) element of \( s \).
- If \( s \) is a particular sequence with \( n \) elements, we may denote \( s \) with the notation \( \langle s_0, s_1, \ldots, s_{n-1} \rangle \).

For example,

\[ \langle \rangle \]

denotes the empty sequence and

\[ \langle 4, 2, 3 \rangle \]

denotes a particular sequence of natural numbers with length three.

- A sequence \( s' \) is said to be a subsequence of a sequence \( s \) if there is a strictly increasing, possibly empty, sequence \( I \) of valid indices into \( s \) such that \( s'_i = s_{I_i} \).
- Sequences can only be ordered if their elements can be ordered. If that condition is met, sequences are ordered lexicographically.

5.2 Signature Definition

```plaintext
signature ST_SEQUENCE =
  sig
    structure Seq : SEQUENCE
```
Figure 5.1: Reduce tree structure for any sequence $s$ with $|s| = 7$

```
type 'a seq = 'a Seq.seq

type 'a stseq
exception Range
val nth : 'a stseq -> int -> 'a
val update : (int * 'a) -> 'a stseq -> 'a stseq
val inject : (int*'a) seq -> 'a stseq -> 'a stseq
val fromSeq : 'a seq -> 'a stseq
val toSeq : 'a stseq -> 'a seq

end
```

### 5.3 Details of Types

### 5.4 Details of Exceptions

#### 5.4.1 Range

*Range* is raised whenever an invalid index into a sequence is used. The specifications for the individual functions state when this will happen more precisely.

This is the only exception that the functions in a module ascribing to *SEQUENCE* raise. An expression applying such a function to appropriate arguments may raise other exceptions, but it will do so only because one of the arguments in that application raised the other exception.

### 5.5 Details of Values

#### 5.5.1 nth: ast seq → int → α

If $s$ is a sequence value and $i$ is an int value and $i$ is a valid index into $s$, then $(\text{nth } s \ i)$ evaluates to $s_i$.

This application raises *Range* if $i$ is not a valid index.
5.5.2  **update**: \((\text{int} \times \alpha) \rightarrow \alpha\text{st seq} \rightarrow \alpha\text{st seq}\)

The call `insert (i,v) S` replaces the \(i^{th}\) location of \(S\) with \(v\) returning a new sequence. Will raise `Range` if \(i\) is out of bounds, i.e., \(i < 0\) or \(i \geq |S|\).

5.5.3  **inject**: \((\text{int} \times \alpha) \text{ seq} \rightarrow \alpha\text{st seq} \rightarrow \alpha\text{st seq}\)

Let \(\text{ind}\) and \(s\) be sequence values and let
\[
\text{occ}(i) := \{ j | \text{ind}_j = (i, x) \text{ for some } x \}\]

\((\text{inject ind s})\) evaluates to the sequence \(s'\) with length \(|s|\), where for all valid indices \(i\) into \(s\)

\[
s'_i = \begin{cases} 
  s_i & \text{occ}(i) = \{ \} \\
  x & j = \text{max(occ}(i)) \land \text{ind}_j = (i, x) 
\end{cases}
\]

This application will raise `Range` if any element of \(\text{ind}\) has a first component that is not a valid index into \(s\).
Chapter 6

TABLE Signature

6.1 Overview

Abstractly, a table is a set of key-value pairs where the keys are unique. For this reason, we often think of it as a mapping that associates each key with a value. Since tables are sets, standard set operations apply on them. We denote by $\emptyset$ an empty table. The size of a table $S$ is the number of keys in $S$ and is rendered $|S|$ in mathematical notation. Furthermore, a table of size $n$ can be written as follows

$$\{(k_1, v_1), (k_2, v_2), \ldots, (k_n, v_n)\},$$

where $k_1, \ldots, k_n$ are $n$ distinct keys and each key $k_i$ maps to $v_i$ for $i \in [n]$. For concreteness, we say that a key $k$ is present in a table $T$, written as $k \in_T T$, if there exists a value $v$ such that $(k, v) \in T$. The documentation that follows states the behavior of operations on this abstraction.

6.2 Signature Definition

```plaintext
signature TABLE =
sig
  type 'a table
  type 'a t = 'a table
  structure Key : EQKEY
  type key = Key.t
  structure Seq : SEQUENCE
  type 'a seq = 'a Seq.seq
  structure Set : SET where type key = key and Seq = Seq
  type set = Set.set
  val empty : unit -> 'a table
  val singleton : key * 'a -> 'a table
  val size : 'a table -> int
  val map : ('a -> 'b) -> 'a table -> 'b table
  val mapk : (key * 'a -> 'b) -> 'a table -> 'b table
  val tabulate : (key -> 'a) -> set -> 'a table
  val domain : 'a table -> set
  val range : 'a table -> 'a seq
  val reduce : ('a * 'a -> 'a) -> 'a -> 'a table -> 'a
  val filter : (key * 'a -> bool) -> 'a table -> 'a table
  val iter : ('b * (key * 'a) -> 'b) -> 'b -> 'a table -> 'b

end
```
val iterh : ('b * (key * 'a) -> 'b) -> 'b -> 'a table -> ('b table * 'b)
val find : 'a table -> key -> 'a option
val merge : ('a * 'a -> 'a) -> ('a table * 'a table) -> 'a table
val mergeOpt : ('a * 'a -> 'a option) -> ('a table * 'a table) -> 'a table
val extract : 'a table * set -> 'a table
val extractOpt : ('a * 'b -> 'c option) -> 'a table * 'b table -> 'c table
val erase : 'a table * set -> 'a table
val insert : ('a * 'a -> 'a) -> (key * 'a) -> 'a table -> 'a table
val delete : key -> 'a table -> 'a table
val fromSeq : (key*'a) seq -> 'a table
val toSeq : 'a table -> (key*'a) seq
val collect : (key*'a) seq -> 'a seq table
val toString : ('a -> string) -> 'a table -> string
end;

6.3 Details of Types

6.3.1 α table
This is the abstract type representing a table with key type key (see below) and value type α.

6.3.2 αt
This type is a shorthand for the abstract type α table representing a table.

6.3.3 key
This indicates that the type of keys in a table has to have type key.

6.4 Details of Values

6.4.1 empty: unit -> α table
empty represents the empty collection ∅.

6.4.2 singleton: key × α -> α table
If k is a value of type key and v is a value of type α, the expression singleton (k,v) evaluates to the collection \{ (k,v) \}.

6.4.3 size: α table -> int
If T is a value of type α table, then size T evaluates to |T| (i.e., the number of keys in the collection T).

6.4.4 map: (α -> β) -> α table -> β table
If f is a function of type α -> β and T is a value of type α table with entries

\{ (k_1,v_1), \ldots, (k_n,v_n) \},

then map f T evaluates to \{ (k_1,f(v_1)), (k_2,f(v_2)), \ldots, (k_n,f(v_n)) \}. That is, it creates a new collection with the same keys by applying f on each value.
6.4.5 \textbf{mapk}: (key \times \alpha \rightarrow \beta) \rightarrow \alpha \text{ table} \rightarrow \beta \text{ table} \\
This function generalizes the \texttt{map} function. If \( f \) is a function of type \( \text{key} \times \alpha \rightarrow \beta \) and \( T \) is a value of type \( \alpha \text{ table} \) with entries \( \{(k_1, v_1), \ldots, (k_n, v_n)\} \), then \texttt{mapk f T} evaluates to \( \{(k_1, f(k_1, v_1)), (k_2, f(k_2, v_2)), \ldots, (k_n, f(k_n, v_n))\} \).

6.4.6 \textbf{tabulate}: (key \rightarrow \alpha) \rightarrow \text{set} \rightarrow \alpha \text{ table} \\
If \( f \) is a function of type \( \text{key} \rightarrow \alpha \) and \( S \) is a value of type \( \text{set} \) with elements \( \{k_1, \ldots, k_n\} \), then \texttt{tabulate f S} evaluates to \( \{(k_1, f(k_1)), (k_2, f(k_2)), \ldots, (k_n, f(k_n))\} \).

6.4.7 \textbf{domain}: \alpha \text{ table} \rightarrow \text{set} \\
For a table \( T \), the function \texttt{domain T} returns the domain of \( T \) as a set.

6.4.8 \textbf{range}: \alpha \text{ table} \rightarrow \alpha \text{ seq} \\
For a table \( T \), the function \texttt{range T} returns the range of \( T \) as a sequence. In particular it is equivalent to \texttt{Seq.map (fn (k, v) \Rightarrow v) (toSeq T)}.

6.4.9 \textbf{reduce}: (\alpha \times \alpha \rightarrow \alpha) \rightarrow \alpha \rightarrow \alpha \text{ table} \rightarrow \alpha \\
The function \texttt{reduce f init T} returns the same as \texttt{Seq.reduce f init (range(T))}.

6.4.10 \textbf{filter}: (key \times \alpha \rightarrow \text{bool}) \rightarrow \alpha \text{ table} \rightarrow \alpha \text{ table} \\
If \( p \) is a predicate and \( T \) is an \( \alpha \text{ table} \) value, then \texttt{filter p T} evaluates to the collection \( T' \) of \( T \) such that \((k, v) \in T \) if and only if \( p \) evaluates to \texttt{true} on \((k, v)\).

6.4.11 \textbf{iter}: (\beta \times (\text{key} \times \alpha) \rightarrow \beta) \rightarrow \beta \rightarrow \alpha \text{ table} \rightarrow \beta \\
If \( f \) is a function, \( b \) is a value, and \( T \) is a table value, then \texttt{iter f b s} iterates \( f \) with left association on \( T \) on an implementation-specified ordering, using \( b \) as the base case. That is, \texttt{iter f b T} evaluates to \( f(f(\ldots f(b, \langle k_1, v_1 \rangle), \ldots, \langle k_2, v_2 \rangle)), \langle k_1, v_1 \rangle) \), where \((k_1, v_1), (k_2, v_2), \ldots, (k_{|T|}, v_{|T|})\) are members of \( T \) listed in the order that the implementation chooses.

6.4.12 \textbf{iterh}: (\beta \times (\text{key} \times \alpha) \rightarrow \beta) \rightarrow \beta \rightarrow \alpha \text{ table} \rightarrow (\beta \text{ table} \times \beta) \\
If \( f \) is a function, \( b \) is a value, and \( T \) is a table value, then \texttt{iterh f b s} iterates \( f \) with left association on \( T \) on an implementation-specified ordering, using \( b \) as the base case. Unlike \texttt{iter}, \texttt{iterh} also stores intermediate results in a table. That is, if the implementation orders \( T \) as \((k_1, v_1), (k_2, v_2), \ldots, (k_{|T|}, v_{|T|})\) and we let \( r_i \) denote the result of the partial evaluation up to the \( i \)-th pair (i.e., \( r_i = f(f(\ldots f(b, \langle k_i, v_i \rangle), \ldots, \langle k_2, v_2 \rangle)), \langle k_1, v_1 \rangle) \)), then \texttt{iterh} evaluates to the pair \( \{(\langle k_i, r_i \rangle : i = 1, \ldots, |T|), r_{|T|}\} \), where \( r_{|T|} = \text{iter f b T} \) by definition.

6.4.13 \textbf{find}: \alpha \text{ table} \rightarrow \text{key} \rightarrow \alpha \text{ option} \\
If \( T \) is a table value and \( k \) is a key value, then \texttt{find T k} evaluates to \texttt{SOME v} provided that \( k \) is present in \( T \) and is associated with the value \( v \); otherwise, it evaluates to \texttt{NONE}.
6.4.14 merge: \((\alpha \times \alpha \to \alpha) \to (\alpha \text{ table } \times \alpha \text{ table}) \to \alpha \text{ table}\)

**merge** is a generalization of set union in the following sense. If \(f\) is a function of type \(\alpha \times \alpha \to \alpha\) and \(S\) and \(T\) are \(\alpha\) tables, then **merge** \(f\) \((S, T)\) evaluates a table with the following properties: (1) it contains all the keys from \(S\) and \(T\) and (2) for each key \(k\), its associated value is inherited from either \(S\) or \(T\) if \(k\) is present in *exactly* one of them. But if \(k\) is present in both tables, i.e., \((k, v) \in S\) and \((k, w) \in T\), then the value is \(f(v, w)\).

6.4.15 mergeOpt: \((\alpha \times \alpha \to \alpha \text{ option}) \to (\alpha \text{ table } \times \alpha \text{ table}) \to \alpha \text{ table}\)

**mergeOpt** further generalizes set union, allowing values to cancel out each other and eliminate the presence of a key in manner similar to set symmetric difference. If \(f\) is a function of type \(\alpha \times \alpha \to \alpha \text{ option}\) and \(S\) and \(T\) are \(\alpha\) tables, then **mergeOpt** \(f\) \((S, T)\) evaluates a table with the following properties: (1) it contains all the keys from \(S\) and \(T\) and (2) for each key \(k\), its associated value is inherited from either \(S\) or \(T\) if \(k\) is present in *exactly* one of them. But if \(k\) is present in both tables, i.e., \((k, v) \in S\) and \((k, w) \in T\), then the following outcomes are possible: in the case that \(f(v, w)\) evaluates to NONE, the key \(k\) will not be present in the output table; otherwise, \(f(v, w)\) evaluates to SOME \(r\) and the key \(k\) will be associated with the value \(r\).

6.4.16 extract: \(\alpha \text{ table } \times \text{ set} \to \alpha \text{ table}\)

**extract** is a generalization of set intersection in the following sense. If \(T\) is an \(\alpha\) table and \(S\) is a set, then **extract** \((T, S)\) evaluates to \(\{(k, v) \in T : k \in_m S\}\).

6.4.17 extractOpt: \((\alpha \times \beta \to \gamma \text{ option}) \to \alpha \text{ table } \times \beta \text{ table} \to \gamma \text{ table}\)

**extractOpt** is a further generalization of set intersection. If \(f\) is a function \(\alpha \times \beta \to \gamma \text{ option}\), \(T\) is an \(\alpha\) table, and \(S\) is a \(\beta\) table, then **extractOpt** \(f\) \((T, S)\) evaluates to \(\{(k, w) : (k, v) \in T, (k, v') \in S, \text{ and } w = f(v, v')\}\).

6.4.18 erase: \(\alpha \text{ table } \times \text{ set} \to \alpha \text{ table}\)

This operation extends set difference. If \(T\) is an \(\alpha\) table, and \(S\) is a set, then **erase** \((T, S)\) evaluates to \(\{(k, v) \in T : (k, v) \in T, k \notin_m S\}\).

6.4.19 insert: \((\alpha \times \alpha \to \alpha) \to (key \times \alpha) \to \alpha \text{ table } \to \alpha \text{ table}\)

For a function \(f\) of type \(\alpha \times \alpha \to \alpha\), a key-value pair \((k, v)\), and a table \(T\), **insert** \(f\) \((k, v)\) \(T\) evaluates to \(T \cup \{(k, v)\}\) provided that \(k \notin_m T\); otherwise, if \((k, v') \in T\), it evaluates to \((T \setminus \{(k, v')\}) \cup \{(k, f(v', v))\}\) (i.e., it replaces the value associated with \(k\) with the result of applying \(f\) on the old value \(v'\) and the new value \(v\)).

6.4.20 delete: \(key \to \alpha \text{ table } \to \alpha \text{ table}\)

If \(k\) is a value of type \(key\) and \(T\) is an \(\alpha\) table, then **delete** \(k\) \(T\) evaluates to \(\{(k', v') \in T : k' \neq k\}\).

6.4.21 fromSeq: \((key \times \alpha) \text{ seq} \to \alpha \text{ table}\)

If \(s\) is a \(key \times \alpha\) sequence such that

\[
s = \{(k_1, v_1), (k_2, v_2), \ldots (k_n, v_n)\},
\]

then **fromSeq** \(s\) evaluates to \(\{(k_1, v_1), (k_2, v_2), \ldots (k_n, v_n)\}\).
6.4.22  \textbf{toSeq}: \(\alpha \text{ table} \rightarrow (\text{key} \times \alpha) \text{ seq}\)

If \(T\) is an \(\alpha\) table representing \\{(k_1, v_1), (k_2, v_2), \ldots, (k_n, v_n)\}, then \textbf{toSeq} \(T\) evaluates to \((k_1, v_1), (k_2, v_2), \ldots, (k_n, v_n)\), where the ordering is determined by the implementation.

6.4.23  \textbf{collect}: \((\text{key} \times \alpha) \text{ seq} \rightarrow \alpha \text{ seq table}\)

This function groups values of the same key together as a sequence of values that respects the original sequence ordering. Specifically, if \(s\) is a \((\text{key} \times \alpha)\) sequence representing \((k_1, v_1), (k_2, v_2), \ldots, (k_n, v_n)\), then \textbf{collect} \(s\) evaluates to \\{\((\ell_1, s_1), (\ell_2, s_2), \ldots, (\ell_m, s_m)\)\}, where the \(\ell_i\)'s are unique keys belonging to \\{k_1, \ldots, k_n\} and for \(i \in [m]\), \(s_i\) is the sequence of values in \(s\) with the key \(\ell_i\) (i.e., \(s_i = (v_j : k_j = \ell_i)\)).
