Lecture 11 — Depth-First Search and Applications

What was covered in this lecture:
- Depth-first Search
- Using DFS for Cycle Detection (undirected and directed graphs) and Topological Sort

1 A Toy Example

Alice is an ambitious freshman who wants to be well-versed in both theory and systems. She plans to take the following classes during her undergraduate career: 15-122, 15-150, 15-210, 15-213, 15-251, 15-359, 15-451, 15-410, 15-412, 15-750, 15-859, and 15-712. But she knows that she should only take one CS class per semester—and most classes have prerequisites that prevent her from getting in right away. According to her research, the course catalog indicates the following prerequisite structure, depicted as a directed graph:

```
  122
   ↓
  213
   ↓
  410
   ↓
  412
```
```
  150
   ↓
  210
   ↓
  451
   ↓
  359
```
```
  251
```
```
  15-750
```
```
  15-712
```
```
  15-859
```

For example, she cannot take 15-451 Algorithms Design and Analysis until she is done with 15-210 and 15-251—although she could take 15-859 Advanced Algorithms or 15-712 Advanced and Distributed Operating Systems in her first semester (after all, most graduate classes don't have any a formal prerequisite list).

We would like to help her construct a schedule to take exactly one CS class per semester. This is known more formally as the topological sort problem or simply TopSort. But before we try to generate a schedule for her, we might be interested in finding out whether the graph has a cycle. In a more general context, what we have is a dependency graph and a cycle in a dependency graph indicates a deadlock. For Alice, this would mean such a schedule doesn't exist and she will never graduate unless she drops some of the classes. In this lecture, we will also look at the cycle detection problem for both directed and undirected graphs.

For both problems, we will develop an algorithm using a graph traversal idea called depth-first search that looks at an edge at most twice!
2 DFS: Depth-First Search

Last time, we looked at breadth-first search (BFS), a graph search technique which, as the name
suggests, explores a graph in the increasing order of hop count from a source node. We’ll spend the
bulk of this lecture discussing another equally-common graph search technique, known as depth-first
search (DFS). Unlike BFS which explores vertices one level at a time in a breadth first manner, the
depth-first search approach proceeds by going as deep as it can until it runs out of unvisited vertices,
at which point it backs out until it finds a node with an unvisited neighbor and goes there in the
same manner.

As with BFS, DFS can be used to find all vertices reachable from a start vertex \( v \), to determine if a
graph is connected, or to generate a spanning tree. Unlike BFS, it cannot be used to find shortest
unweighted paths. But, instead, it is useful in some other applications such as topologically sorting a
directed graph (TopSort), cycle detection, or finding the strongly connected components (SCC) of a
graph. We will touch on some of these problems briefly.

**Example 2.1.** To contrast BFS with DFS, let’s consider the following simple V-shaped graph:

In this example, a BFS starting from \( s \) will first visit \( s \), then visit vertices at distance 1 from \( s \) (1 and 4),
then vertices at distance 2 from \( s \) (2 and 5), then vertices at distance 3 away (3 and 6)—and we’re done.
Whereas, a DFS starting from \( s \) will go as deep as it can: at \( s \), we could go to 1 or 4 as the first vertex.
Suppose we choose 1, then we will proceed to visit 2 and 3, then after hitting a dead end, we back out to
2 then back to 1, and proceed down 4 to 5 to 6 and back out.

**Example 2.2.** As another example, we’ll look at a slightly more complicated version of the graph above,
where we join the nodes 2 and 5 together with an edge.
Nothing changes when we run BFS despite that extra edge between 2 and 5; however, the order in which DFS visits vertices changes drastically. Suppose we start at s and choose to go down node 1 first. We will visit 2, 3, then back out to 2, then since 2 has 5 as its neighbor, we’ll visit 5, which in turn, will take us to 4 and to s, but s has been visited before, so we won’t visit that—we back out. We’ll then go to 5, 6, back to 5, to 2, to 1, to s. We will try to visit 4 but quickly realize that 4 has been visited, so again, we back out.

How do we turn this idea into code? We first consider a simple version of depth-first search that simply returns a set of reachable vertices. Notice that in this case, the algorithm returns exactly the same set as BFS—but the crucial difference is that DFS visits the vertices in a different order (depth vs. breadth). Here is the code:

```
function DFS(G, s) =
  function DFS'(X, v) =
    if (v ∈ X)
      TOUCH v
      then X
    else let
      ENTER v
      X' = X ∪ {v}
      X'' = iter DFS' X' (NG(v))
      EXIT v
      in X'' end
    in DFS'({}, s) end
```

The helper function DFS'(X, v) does all the work. X is the set of already visited vertices (as in BFS) and v is a single vertex we want to explore from. The code first tests if v has already been visited and returns if so. Otherwise it visits the vertex v by adding it to X (line ENTER v), iterating itself recursively on all neighbors, and finally returning the updated set of visited vertices (line EXIT v). Recall that (iter f s₀ A) iterates over the elements of A starting with a state s₀. Each iteration uses the function f : α × β → α to map a state of type α and element of type β to a new state. It can be thought of as:

```
S = s₀
foreach a ∈ A:
  S = f(S, a)
return S
```
For a sequence \texttt{iter} processes the elements in the order of the sequence, but since sets are unordered the ordering of \texttt{iter} will depend on the implementation.

What this means for the DFS algorithm is that when the algorithm visits a vertex \(v\) (i.e., reaches the line \texttt{ENTER \(v\)}, it picks the first outgoing edge \((v,w_1)\), through \texttt{iter}, calls \texttt{DFS'}\((X \cup \{v\}, w_1)\) to explore the unvisited vertices reachable from \(w_1\). When the call \texttt{DFS'}\((X \cup \{v\}, w_1)\) returns the algorithm has fully explored the graph reachable from \(w_1\) and the vertex set returned (call it \(X_1\)) includes all vertices in the input \(X \cup v\) plus all vertices reachable from \(w_1\). The algorithm then picks the next edge \((v,w_2)\), again through \texttt{iter}, and fully explores the graph reachable from \(w_2\) starting with the the vertex set \(X_1\). The algorithm continues in this manner until it has fully explored all out-edges of \(v\). At this point, \texttt{iter} is complete—and \(X''\) includes everything in the original \(X' = X \cup \{v\}\) as well as everything reachable from \(v\).

**Touching, Entering, and Exiting.** There are three points in the code that are particularly important since they play a role in various proofs of correctness and also these are the three points at which we will add code for various applications of DFS. The points are labeled on the left of the code. The first point is \texttt{TOUCH \(v\)} which is the point at which we try to visit a vertex \(v\) but it has already been visited and hence added to \(X\). The second point is \texttt{ENTER \(v\)} which is when we first encounter \(v\) and before we process its out edges. The third point is \texttt{EXIT \(v\)} which is just after we have finished visiting the out-neighbors and are returning from visiting \(v\). At the exit point all vertices reachable from \(v\) must be in \(X\).

**Exercise 1.** At \texttt{ENTER \(v\)} can any of the vertices reachable from \(v\) already be in \(X\)? Answer this both for directed and separately for undirected graphs.

**Is DFS parallel?** At first look, we might think this approach can be parallelized by searching the out edges in parallel. This would indeed work if the searches initiated never “meet up” (e.g., the graph is a tree so paths never meet up). However, when the graphs reachable through the outgoing edges are shared, visiting them in parallel creates complications because we don’t want to visit a vertex twice and we don’t know how to guarantee that the vertices are visited in a depth-first manner.

To understand the situation better, we’ll look at a simple example: a cycle graph on 6 nodes \((C_6)\). The left figure shows a 6-cycle \(C_6\) with nodes \(s, a, b, c, d, e\) and the right figure shows the order (as indicated by the arrows) in which the vertices are visited as a result of starting at \(s\) and first visiting \(a\).

In this example, since the search wraps all the way around, we couldn't know until the end that \(e\) would be visited (in fact, it got visited last), so we couldn't start searching \(s\)'s other neighbor \(e\) until we are done searching the graph reachable from \(a\). More generally, in an undirected graph, if two
unvisited neighbors $u$ and $v$ have any reachable vertices in common, then whichever is explored first will always wrap all the way around and visit the other one.

Indeed, depth-first search is known to be P-complete, a class of computations that can be done in polynomial work but are widely believed that they do not admit a polylogarithmic span algorithm. A detailed discussion of this topic is beyond the scope of our class. But this provides further evidence that DFS might not be highly parallel.

**Cost of DFS**  The cost of DFS will depend on what data structures we use to implement the set, but generally we can bound it by counting how many operations are made and multiplying it by the cost of each operation. In particular we have the following

**Lemma 2.3.** For a graph $G = (V, E)$ with $m$ out edges, and $n$ vertices, DFS$'$ will be called at most $m$ times and a vertex will be entered for visiting at most $\min(n,m)$ times.

**Proof.** Every vertex will be visited at most once since we always add them to $X$ when we enter so the test $v \in X$ can only fail $n$ times. Every out-edge will only be traversed once invoking a call to DFS$'$ since its vertex is only visited once, so at most $m$ calls will be made to DFS$'$. Finally we can only enter a vertex once per call to DFS$'$ so the number of enters is bounded by $\min(n,m)$.

Note that each time we enter DFS$'$ we do one check to see if if $v \in X$. For each time we enter a vertex for visiting we do one insertion of $v$ into $X$. We therefore do at most $\min(m, n)$ insertions and $m$ finds. This gives:

**Corollary 2.4.** The DFS algorithm a graph with $m$ out edges, and $n$ vertices, and using the tree-based cost specification for sets runs in $O(m \log n)$ work and span.

Later we will consider a version based on single threaded sequences that reduces the work and span to $O(n + m)$.

### 3 Cycle Detection: Undirected Graphs

We now consider some other applications of DFS beyond just reachability. Given a graph $G = (V, E)$ cycle detection problem is to determine if there are any cycles in the graph. The problem is different depending on whether the graph is directed or undirected, and here we will consider the undirected case. Later we will also look at the directed case.

How would we modify the generic DFS algorithm above to solve this problem? A key observation is that in an undirected graph if DFS$'$ ever arrives at a vertex $v$ a second time, and the second visit is coming from another vertex $u$ (via the edge $(u, v)$), then there must be two paths between $u$ and $v$: the path from $u$ to $v$ implied by the edge, and a path from $v$ to $u$ followed by the search between when $v$ was first visited and $u$ was visited. Since there are two distinct paths, there is a “cycle”. Well not quite! Recall that in an undirected graph a cycle must be of length at least 3, so we need to be careful not to consider the two paths $(u, v)$ and $(v, u)$ implied by the fact the edge is bidirectional (i.e. a length 2 cycle). It is not hard to avoid these length two cycles. These observations lead to the following code.
function undirectedCycle(G, s) = let
    function DFS′ p ((X, C), v) =
        if (v ∈ X)
            TOUCH v
            then (X, true)
        else let
            ENTER v:
            X′ = X ∪ {v}
            (X′′, C′) = iter (DFS′ v) (X′, C) (NG(v) \ {p})
        in
            EXIT v:
            in (X′′, C′) end
        in
            DFS′ s (({}, false), s) end

The code returns both the visited set and whether there is a cycle. The key differences from the generic DFS are underlined. The variable C is a boolean variable indicating whether a cycle has been found so far. It is initially set to false and set to true if we find a vertex that has already been visited. The extra argument p to DFS′ is the parent in the DFS tree, i.e. the vertex from which the search came from. It is needed to make sure we do not count the length 2 cycles. In particular we remove p from the neighbors of v so the algorithm does not go directly back to p from v. The parent is passed to all children by “currying” using the partially applied (DFS′ v). If the code executes the TOUCH v line then it has found a path of at least length 2 from v to p and the length 1 path (edge) from p to v, and hence a cycle.

Exercise 2. In the final line of the code the initial “parent” is the source s itself. Why is this OK for correctness?

4 Topological Sorting

We now return to topological sorting as a second application of DFS.

Directed Acyclic Graphs. A directed graph that has no cycles is called a directed acyclic graph or DAG. DAGs have many important applications. They are often used to represent dependence constraints of some type. Indeed, one way to view a parallel computation is as a DAG where the vertices are the jobs that need to be done, and the edges the dependences between them (e.g. a has to finish before b starts). Mapping such a computation DAG onto processors so that all dependences are obeyed is the job of a scheduler. You have seen this briefly in 15-150. The graph of dependencies cannot have a cycle, because if it did then the system would deadlock and not be able to make progress.

The idea of topological sorting is to take a directed graph that has no cycles and order the vertices so the ordering respects reachability. That is to say, if a vertex u is reachable from v, then v must be lower in the ordering. In other words, if we think of the input graph as modeling dependencies (i.e., there is an edge from v to u if u depends on v), then topological sorting finds a partial ordering that puts a vertex after all vertices that it depends on.

To make this view more precise, we observe that a DAG defines a so-called partial order on the vertices in a natural way:
For vertices \( a, b \in V(G) \), \( a \leq_p b \) if and only if there is a directed path from \( a \) to \( b \).\(^1\)

Remember that a partial order is a relation \( \leq_p \) that obeys

1. reflectivity — \( a \leq_p a \),
2. antisymmetry — if \( a \leq_p b \) and \( b \leq_p a \), then \( b = a \), and
3. transitivity — if \( a \leq_p b \) and \( b \leq_p c \) then \( a \leq_p c \).

In this particular case, the relation is on the vertices. It's not hard to check that the relation based on reachability we defined earlier satisfies these 3 properties. Armed with this, we can define the topological sorting problem formally:

**Problem 4.1 (Topological Sorting(T\textsc{opsort}))**. A topological sort of a DAG is a total ordering \( \leq_t \) on the vertices of the DAG that respects the partial ordering (i.e. \( a \leq_p b \) then \( a \leq_t b \), though the other direction needs not be true).

For instance, consider the following DAG:

![DAG diagram](image)

We can see, for example, that \( a \leq_p c \), \( d \leq h \), and \( c \leq h \). But it is a partial order: we have no idea how \( c \) and \( g \) compare. From this partial order, we can create a total order that respects it. One example of this is the ordering \( a \leq_t b \leq_t d \leq_t e \leq_t f \leq_t g \leq_t h \). Notice that, as this example graph shows, there are many valid topological orderings.

**Solving T\textsc{opsort} using DFS.** To topologically sort a graph, we augment our directed graph \( G = (V, D) \) with a new source vertex \( s \) and a set of directed edges from the source to every vertex, giving \( G' = (V \cup \{s\}, E \cup \{(s, v) : v \in V\}) \). We then run the following variant of DFS on \( G' \) starting at \( s \):

```plaintext
function topSort(G = (V,E)) =
  s = a new vertex
  G' = (V \cup \{s\}, E \cup \{(s, v) : v \in V\})

  function DFS'((X, L), v) =
    if (v \in X)
      TOUCH v
      then (X, L)
    else let
      X' = X \cup \{v\}
      (X'', L') = \text{iter DFS'} (X', L) (N_{G'}(v))
      in (X'', v :: L') end
    in DFS'((\{\}, []) , s) end
```

\(^1\)We adopt the convention that there is a path from \( a \) to \( a \) itself, so \( a \leq_p a \).
The significant changes from the generic version are marked with underlines. In particular we thread a list $L$ through the search. The only thing we do with this list is cons the vertex $v$ onto the front of it when we exit DFS for vertex $v$ (line $\text{EXIT } v$). We claim that at the end, the ordering in the list returned specifies a topological sort of the vertices, with the earliest at the front.

**Why is this correct?** The correctness crucially follows from the property that DFS fully searches any unvisited vertices that are reachable from it before returning. In particular the following theorem is all that is needed.

**Theorem 4.2.** On a DAG when exiting a vertex $v$ in DFS all vertices reachable from $v$ have already exited.

**Proof.** This theorem might seem obvious, but we have to be a bit careful. Consider a vertex $u$ that is reachable from $v$ and consider the two possibilities of when $u$ is entered relative to $v$.

1. $u$ is entered before $v$ is entered. In this case $u$ must also have exited before $v$ is entered otherwise there would be a path from $u$ to $v$ and hence a cycle.

2. $u$ is entered after $v$ is entered. In this case since $u$ is reachable from $v$ it must be visited while searching $v$ and therefore exit before $v$ exits. \(\square\)

This theorem implies the correctness of the code for topological sort. This is because it places vertices on the front of the list in exit order so all vertices reachable from a vertex $v$ will appear after it in the list, which is the property we want.

### 5 Cycle Detection: Directed Graphs

We now return to cycle detection but in the directed case. This can be an important preprocessing step for topological sort since topological sort will return garbage for a graph that has cycles. As with topological sort, we augment the input graph $G = (V,E)$ by adding a new source $s$ with an edge to every vertex $v \in V$. Note that this modification cannot add a cycle since the edges are all directed out of $s$. Here is the code:

```plaintext
: function directedCycle(G = (V,E)) = let
  s = a new vertex
  G' = (V \cup \{s\}, E \cup \{(s,v) : v \in V\})

  : function DFS'((X, Y, C), v) =
  :   if (v \in X)
  :     then (X, Y, v \in Y)
  :     else let
  :       TOUCH v :
  :       ENTER v :
  :       X' = X \cup \{v\}
  :       Y' = Y \cup \{v\}
  :       (X'', Y'', C') = iter DFS' (X', Y', C) (N_G(v))
  :     EXIT v :
  :     in (X'', Y'' \setminus \{v\}, C') end

  :   (\_, \_, C) = DFS'((\_), (\_), false), s)
  : in C end
```

8
The differences from the generic version are once again underlined. In addition to threading a boolean value $C$ through the search that keeps track of whether there are any cycles, it threads the set $Y$ through the search. When visiting a vertex $v$, the set $Y$ contains all vertices that are ancestors of $v$ is the DFS tree. This is because we add a vertex to $Y$ when entering the vertex and remove it when exiting. Therefore, since recursive calls are properly nested, the set will contain exactly the vertices on the recursion path from the root to $v$, which are also the ancestors in the DFS tree.

To see how this helps we define a back edge in a DFS search to be an edge that goes from a vertex $v$ to an ancestor $u$ in the DFS tree.

**Theorem 5.1.** A directed graph $G = (V, E)$ has a cycle if and only if for $G' = (V \cup \{s\}, E \cup \{(s, v) : v \in V\})$ a DFS from $s$ has a back edge.

**Exercise 3.** Prove this theorem.

### 5.1 Generalizing DFS

As already described there is a common structure to all the applications of DFS—they all do their work either when “entering” a vertex, when “exiting” it, or when “touching” it, i.e. attempting to visit when already visited. This suggests that we might be able to derive a generic version of DFS in which we only need to supply functions for these three components. This is indeed possible by having the user define a state of type $\alpha$ that can be threaded throughout search, and then supplying and an initial state and three functions:

$$
\begin{align*}
\Sigma_0 & : \alpha \\
touch & : \alpha \times \text{vertex} \times \text{vertex} \rightarrow \alpha \\
ten & : \alpha \times \text{vertex} \times \text{vertex} \rightarrow \alpha \\
exit & : \alpha \times \text{vertex} \times \text{vertex} \rightarrow \alpha
\end{align*}
$$

where each function takes the state, the current vertex $v$, and the parent vertex $p$ in the DFS tree, and returns an updated state. The code can then be written as:

```plaintext
1 function DFS(G, \Sigma_0, s) = let
2 function DFS’ p ((X, \Sigma), v) =
3     if (v \in X) then (X, touch(\Sigma, v, p))
4     else let
5         \Sigma’ = enter(\Sigma, v, p)
6         (X’, \Sigma’’) = iter(DFS’ p) (X \cup \{v\}, \Sigma’') N^+_G(v)
7         \Sigma’’’ = exit(\Sigma, \Sigma’’, v, p)
8     in (X’, \Sigma’’’) end
9     in DFS’ s ((\emptyset, \Sigma_0), s) end
```

At the end, DFS returns an ordered pair $(X, \Sigma) : \text{Set} \times \alpha$, which represents the set of vertices visited and the final state $\Sigma$.

With this code we can easily define our applications of DFS. For undirected cycle detection we have:
\[ \Sigma_0 = ([s], \text{false}) : \text{vertex list} \times \text{bool} \]

function touch\((h :: T, f1, v, p) = (L, h \neq p)\)
function enter\((L, f1, v, p) = (v :: L, f1)\)
function exit\((h :: T, f1, v, p) = (T, f1)\)

For topological sort we have.

\[ \Sigma_0 = [] : \text{vertex list} \]
function touch\((L, v, p) = L\)
function enter\((L, v, p) = L\)
function exit\((L, v, p) = v :: L\)

For directed cycle detection we have.

\[ \Sigma_0 = (\{\}, \text{false}) : \text{Set} \times \text{bool} \]
function touch\((S, f1, v, p) = (S, v \in? S)\)
function enter\((S, f1, v, p) = (S \cup \{v\}, f1)\)
function exit\((S, f1, v, p) = (S \setminus \{v\}, f1)\)

For these last two cases we need to also augment the graph with the vertex \(s\) and add the the edges to each vertex \(v \in V\).

## 6 DFS with Single-Threaded Arrays

Here is a version of DFS using adjacency sequences for representing the graph and ST sequences for keeping track of the visited vertices.

```plaintext
1 function DFS\((G : (\text{int seq}) \text{ seq}, s : \text{int}) =
2   let
3     function DFS'\ p ((X : \text{bool stseq, } \Sigma), v : \text{int}) =
4       if \(X[v]\) then \((X, \text{touch}(\Sigma, v, p))\)
5       else let
6         \(X' = \text{update}(v, \text{true}, X)\)
7         \(\Sigma' = \text{enter}(\Sigma, v, p)\)
8         \((X'', \Sigma'') = \text{iter}(\text{DFS'} v) (X', \Sigma') (G[v])\)
9       in \((x'', \text{exit}(\Sigma'', v, p))\)
10      \(X_{\text{init}} = \text{stSeq.fromSeq}((\text{false} : v \in \langle 0, \ldots, |G| - 1 \rangle))\)
11    in \n12      stSeq.toSeq(DFS'\((X_{\text{init}}, \Sigma_0), s)\))
13 end
```

If we use an stseq for \(X\) (as indicated in the code) then this algorithm uses \(O(m)\) work and span. However if we use a regular sequence, it requires \(O(n^2)\) work and \(O(m)\) span.
7 SML Code

Here we give the SML code for the generic version of DFS along with the implementation of directed cycle detection and topological sort.

signature DFSops =
  sig
    type vertex
    type state
    val start : state
    val enter : state * vertex * vertex -> state
    val exit : state * vertex * vertex -> state
    val touch : state * vertex * vertex -> state
  end

  structure Ops : DFSops
  sharing type Ops.vertex = Table.Key.t) =
  struct
    open Ops
    open Table
    type graph = set table

    fun N(G : graph, v : vertex) =
      case (Table.find G v) of
        NONE => Set.empty
      | SOME(ngh) => ngh

    fun dfs (G : graph, s : vertex) =
      let
        fun dfs' p ((X : set, S : state), v : vertex) =
          if (Set.find X v) then (X, touch(S,p,v))
          else
            let
              val X' = Set.insert v X
              val S' = enter(S, p, v)
              val (X'',S'') = Set.iter (dfs' p) (X',S') (N(G,v))
              val S'''' = exit(S''', p, v)
              in
                dfs'' S''''
              end
            in
              dfs' s ((Set.empty, start), s)
            end
      end

  end

functor CycleCheck(Table : TABLE) = DFS(
  structure Table = Table
  structure Ops =
  struct
    structure Set = Table.Set
