

Lecture 17:

Implementing Synchronization

Parallel Computer Architecture and Programming
CMU 15-418/15-618, Spring 2021

Today's topic: efficiently implementing synchronization primitives

- Primitives for ensuring mutual exclusion
 - Locks
 - Atomic primitives (e.g., atomic_add)
 - Transactions (later in the course)
- Primitives for event signaling
 - Barriers
 - Flags

Three phases of a synchronization event

1. Acquire method
 - How a thread attempts to gain access to protected resource
2. Waiting algorithm
 - How a thread waits for access to be granted to shared resource
3. Release method
 - How thread enables other threads to gain resource when its work in the synchronized region is complete

Busy waiting

- **Busy waiting (a.k.a. “spinning”)**

```
while (condition X not true) {}
```

logic that assumes X is true

- In classes like 15-213 or in operating systems, you have certainly also talked about synchronization
 - You might have been taught busy-waiting is bad: why?

“Blocking” synchronization

- Idea: if progress cannot be made because a resource cannot be acquired, it is desirable to free up execution resources for another thread (preempt the running thread)

```
if (condition X not true)
    block until true; // os scheduler de-schedules thread
                      // (let's another thread use the processor)
```

- pthreads mutex example

```
pthread_mutex_t mutex;
pthread_mutex_lock(&mutex);
```

Busy waiting vs. blocking

- Busy-waiting can be preferable to blocking if:
 - Scheduling overhead is larger than expected wait time
 - **Processor's resources not needed for other tasks**
 - **This is often the case in a parallel program since we usually don't oversubscribe** a system when running a performance-**critical parallel app (e.g., there aren't** multiple CPU-intensive programs running at the same time)
 - Clarification: be careful to not confuse the above statement with the value of multi-threading (interleaving execution of multiple threads/tasks to hiding long latency of memory operations) with other work within the same app.

- Examples:

```
pthread_spinlock_t spin;  
pthread_spin_lock(&spin);
```

```
int lock;  
OSSpinLockLock(&lock); // OSX spin lock
```

Implementing Locks

Warm up: a simple, but incorrect, lock

```
lock:      ld   R0, mem[addr]      // load word into R0
            cmp  R0, #0           // compare R0 to 0
            bnz lock             // if nonzero jump to top
            st   mem[addr], #1

unlock:    st   mem[addr], #0      // store 0 to address
```

Problem: data race because LOAD-TEST-STORE is not atomic!

Processor 0 loads address X, observes 0

Processor 1 loads address X, observes 0

Processor 0 writes 1 to address X

Processor 1 writes 1 to address X

Test-and-set based lock

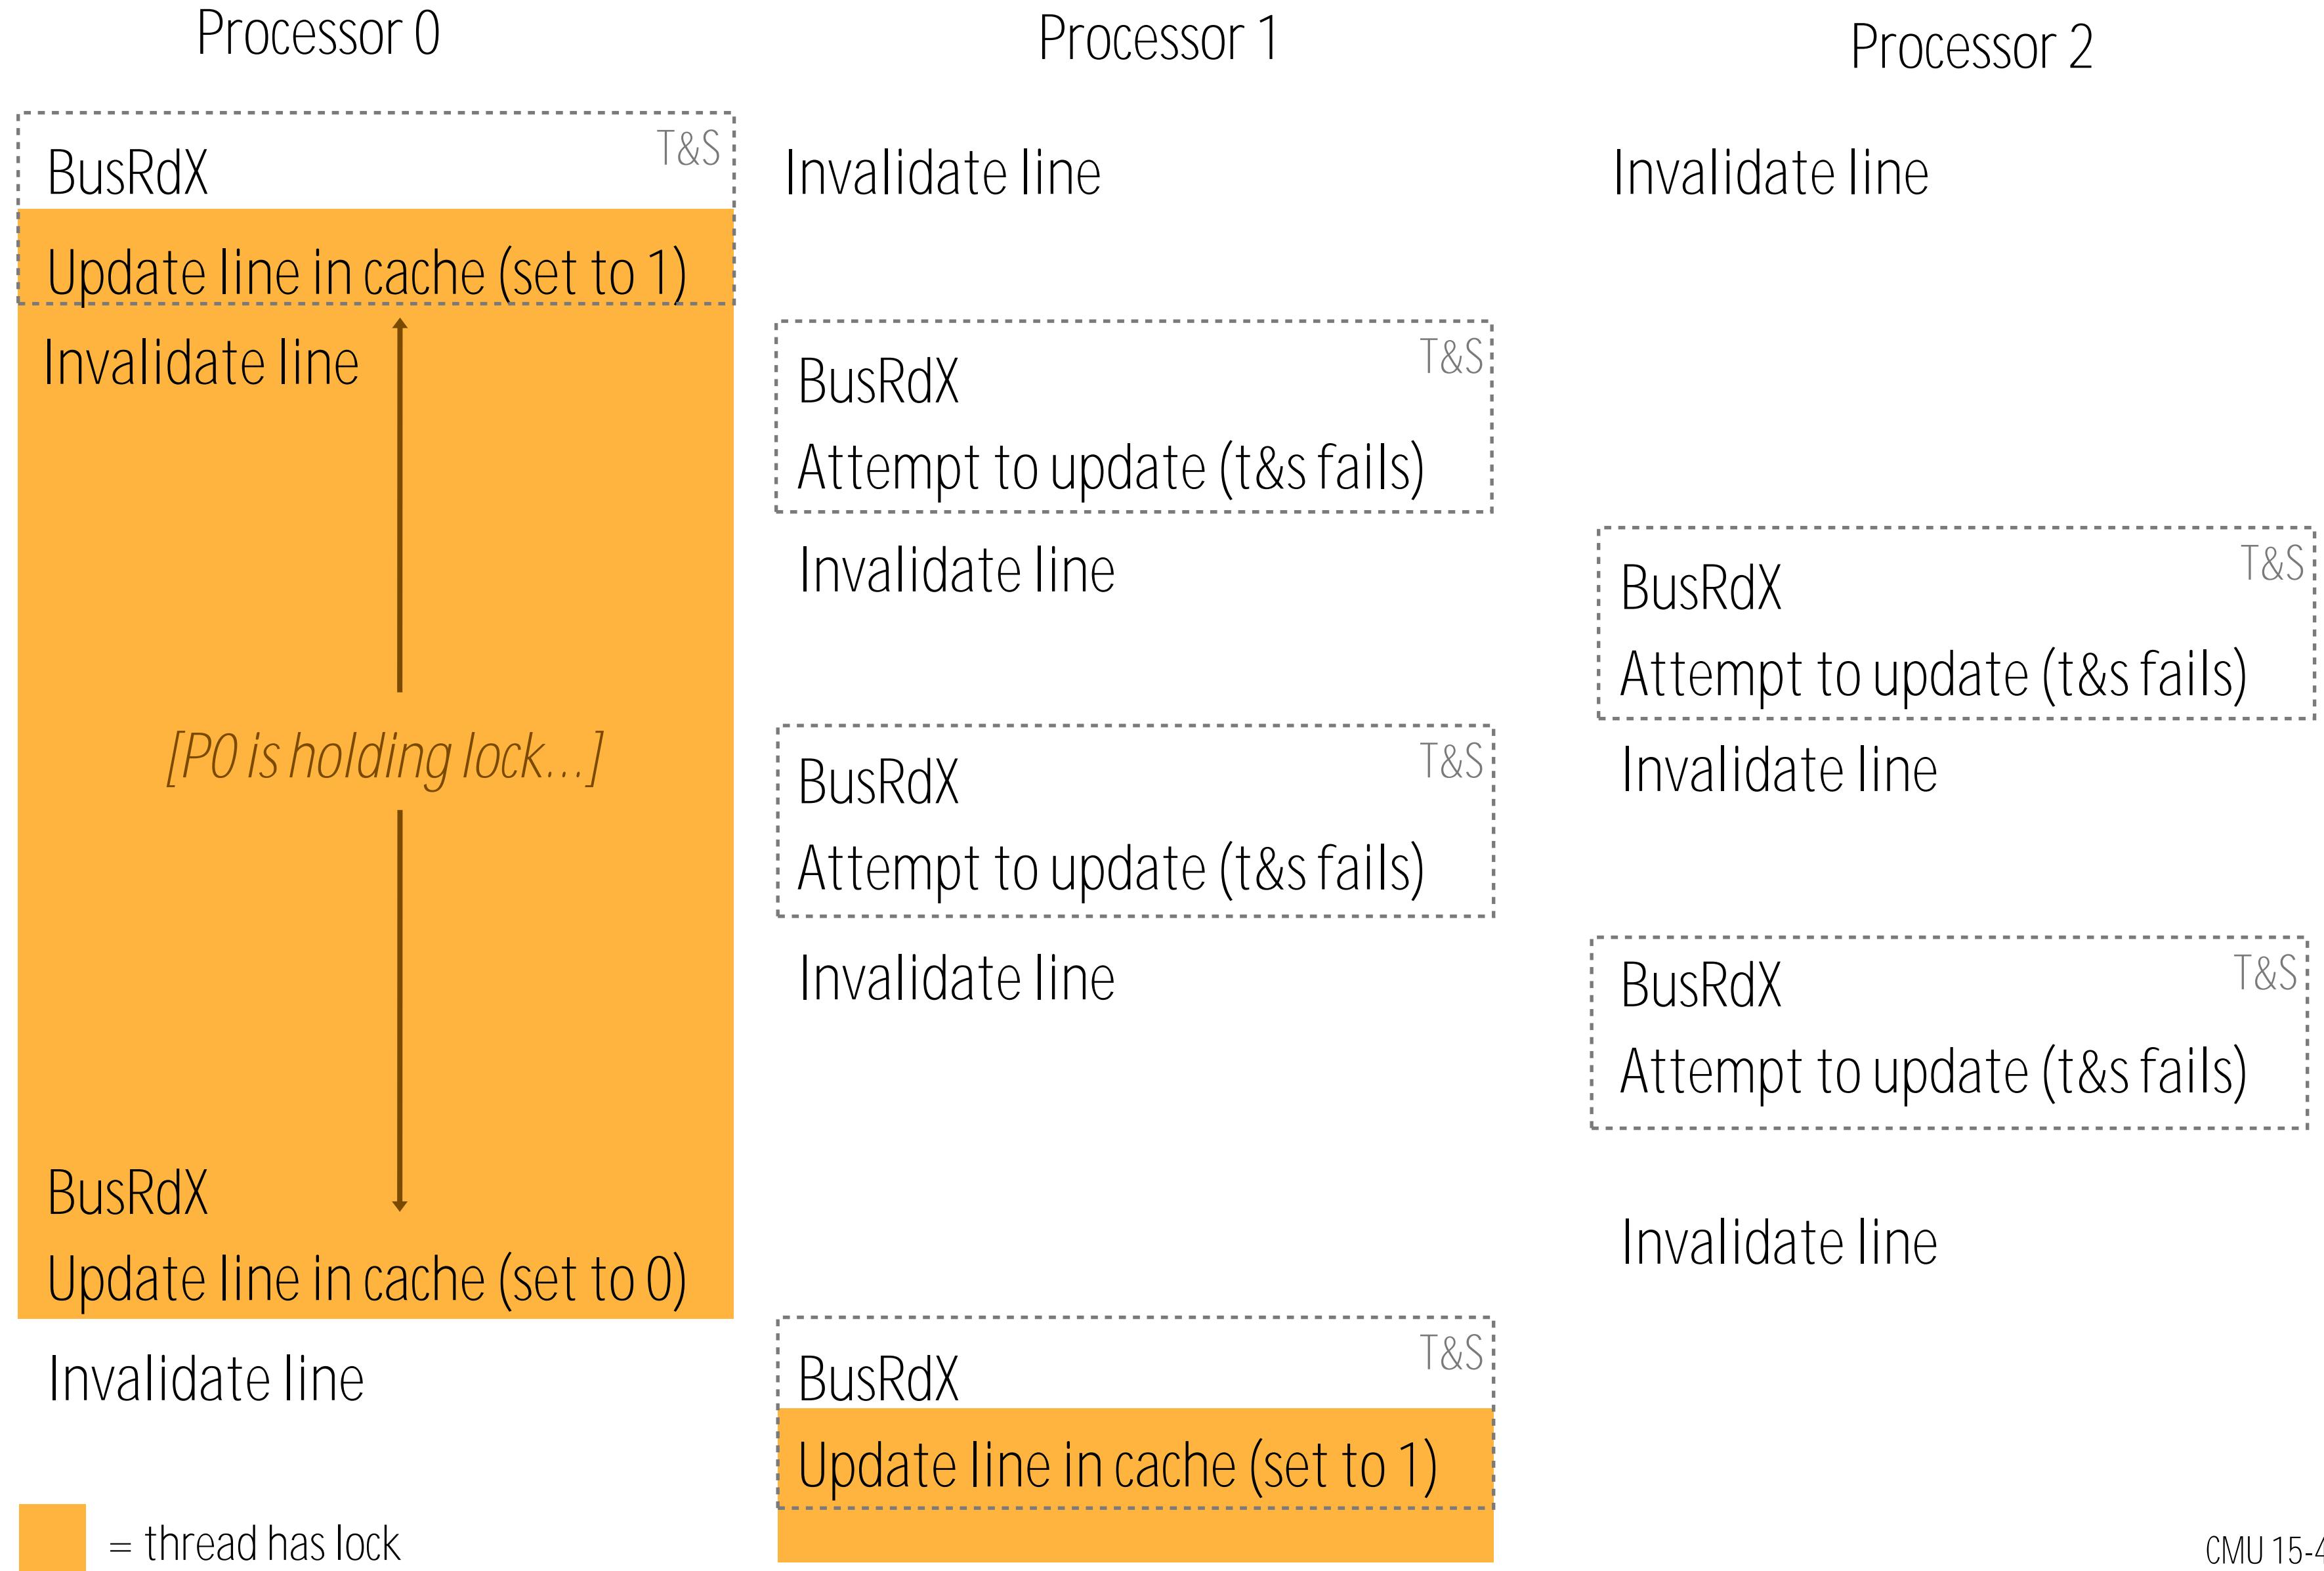

Atomic test-and-set instruction:

```
ts R0, mem[addr]          // load mem[addr] into R0
                           // if mem[addr] is 0, set mem[addr] to 1
```

```
lock:      ts R0, mem[addr]          // load word into R0
           bnz R0, lock            // if 0, lock obtained
```

```
unlock:    st mem[addr], #0          // store 0 to address
```

Test-and-set lock: consider coherence traffic

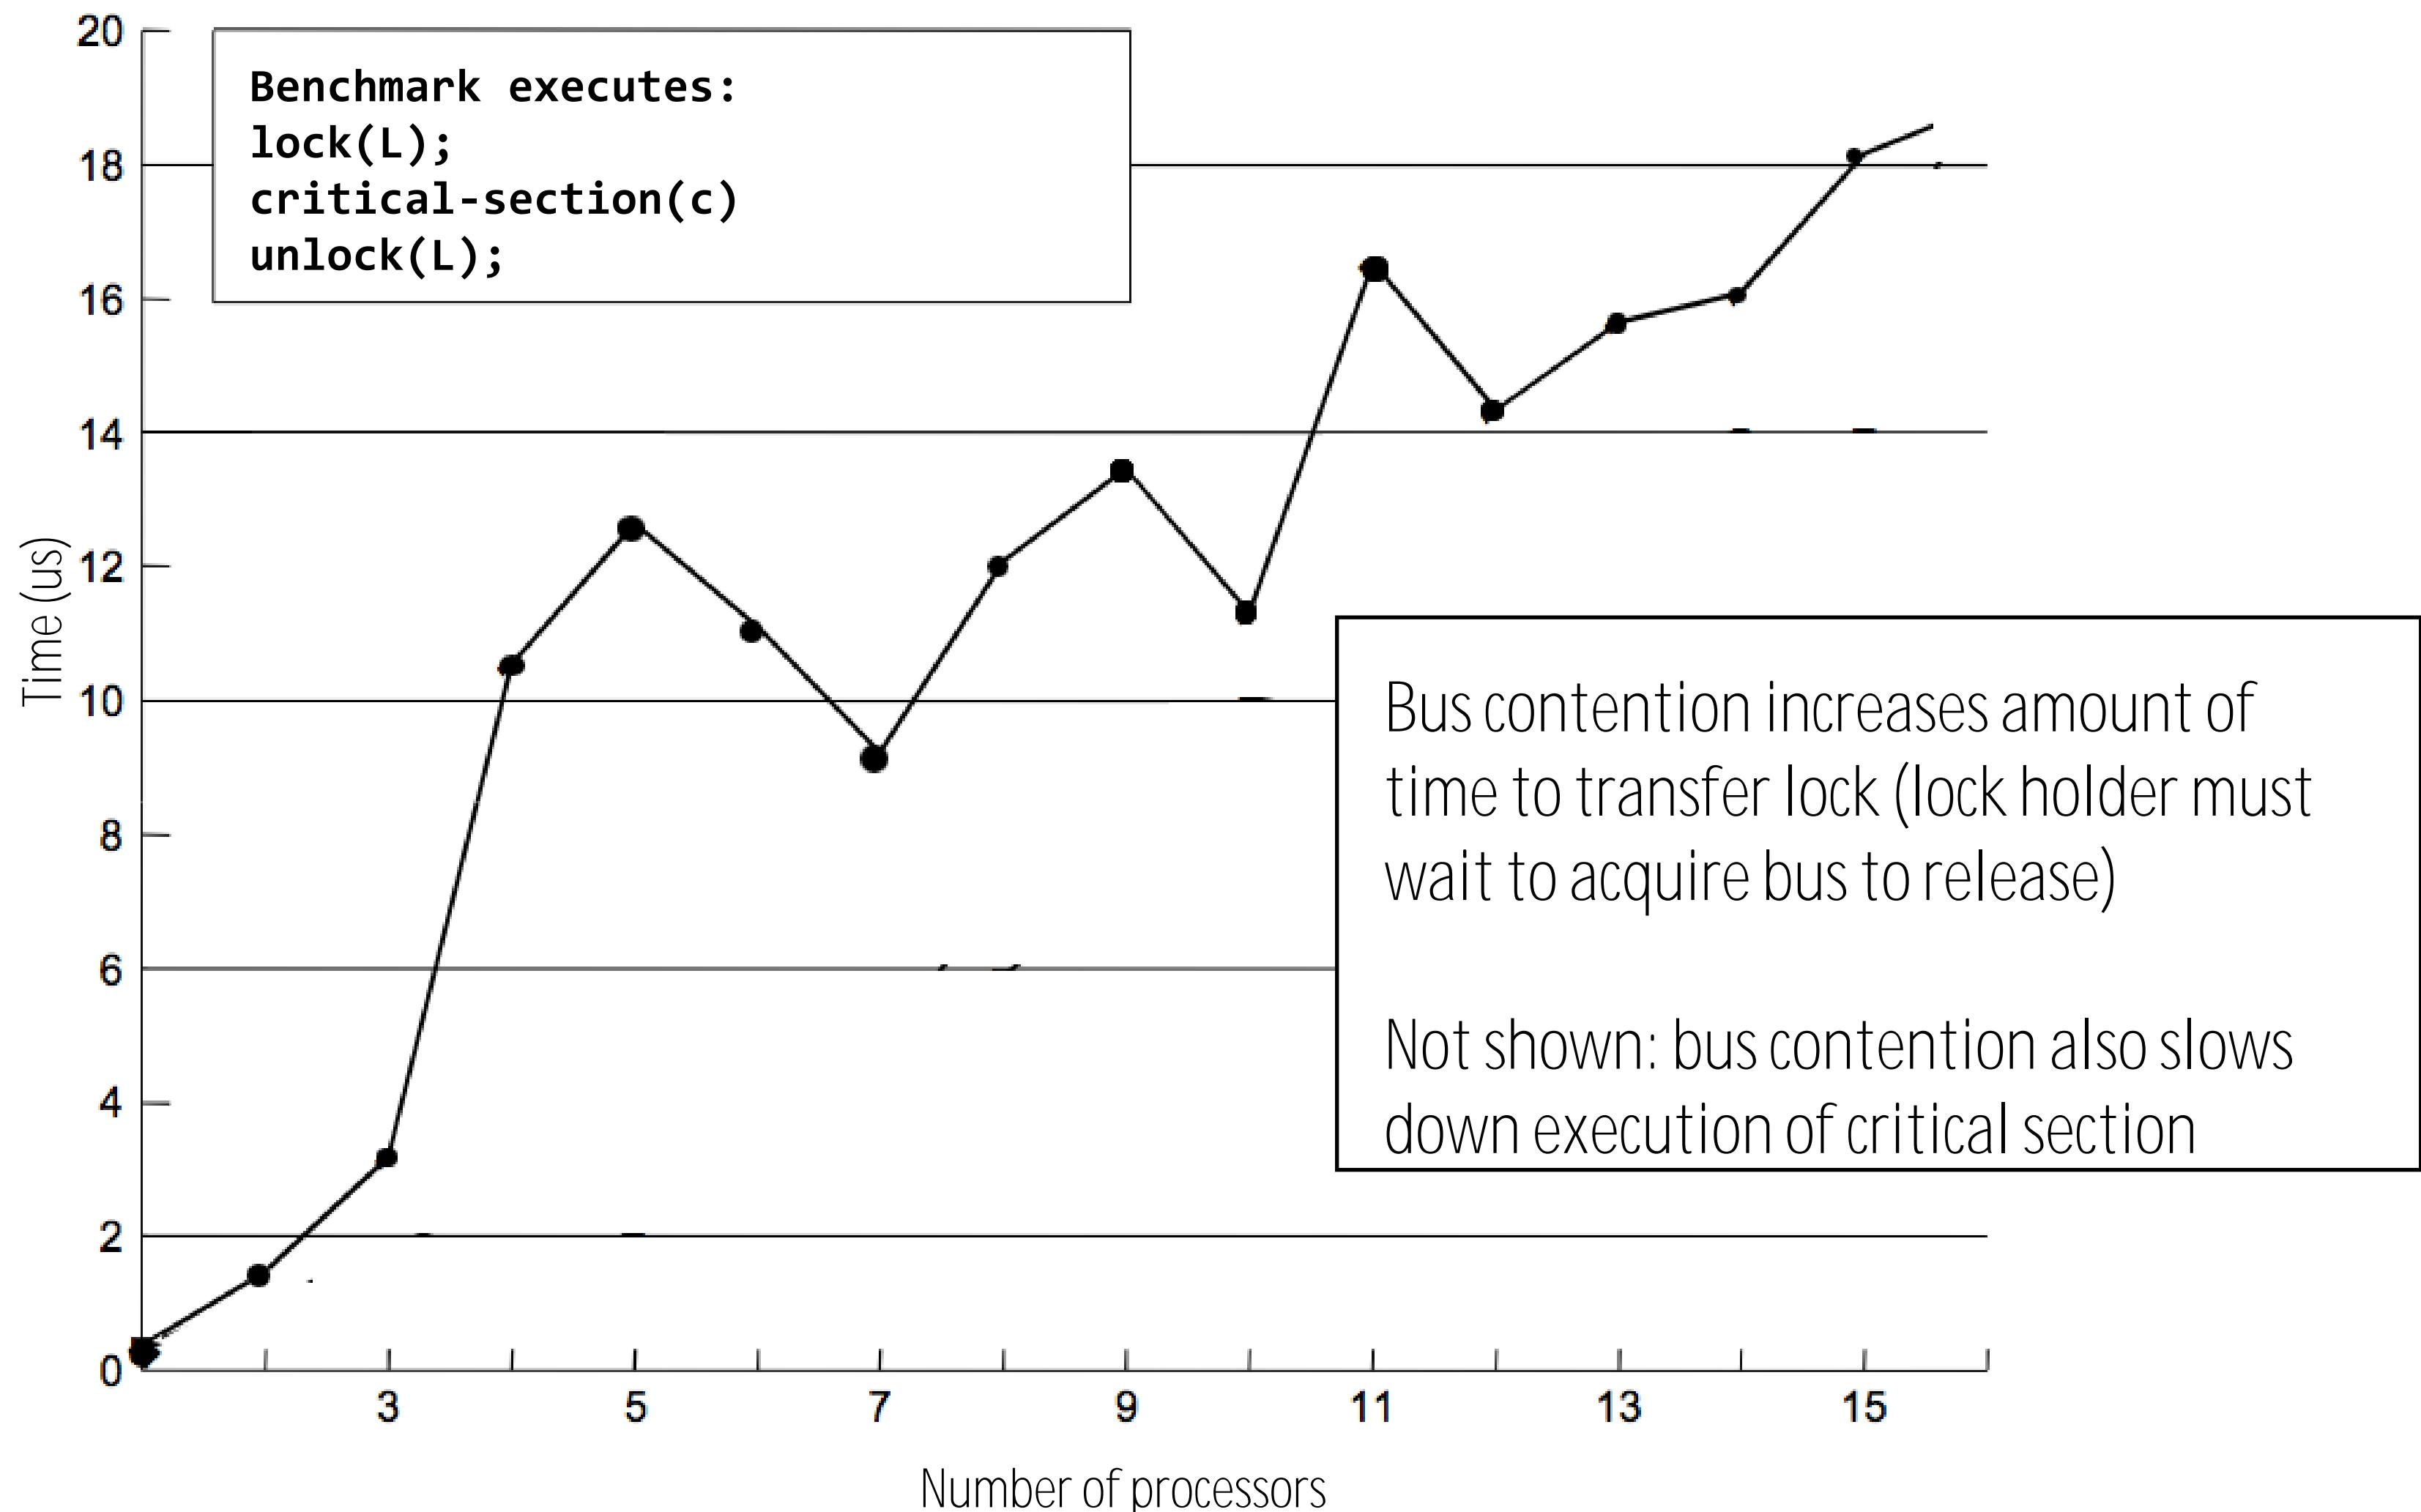

Check your understanding

- On the previous slide, what is the duration of time the thread running on P0 holds the lock?
- **At what points in time does P0's cache contain a valid copy of** the cache line containing the lock variable?

Test-and-set lock performance

Benchmark: execute a total of N lock/unlock sequences (in aggregate) by P processors

Critical section time removed so graph plots only time acquiring/releasing the lock

Desirable lock performance characteristics

- Low latency
 - If lock is free and no other processors are trying to acquire it, a processor should be able to acquire the lock quickly
- Low interconnect traffic
 - If all processors are trying to acquire lock at once, they should acquire the lock in succession with as little traffic as possible
- Scalability
 - Latency / traffic should scale reasonably with number of processors
- Low storage cost
- Fairness
 - Avoid starvation or substantial unfairness
 - One ideal: processors should acquire lock in the order they request access to it

Simple test-and-set lock: low latency (under low contention), high traffic, poor scaling, low storage cost (one int), no provisions for fairness

Test-and-test-and-set lock

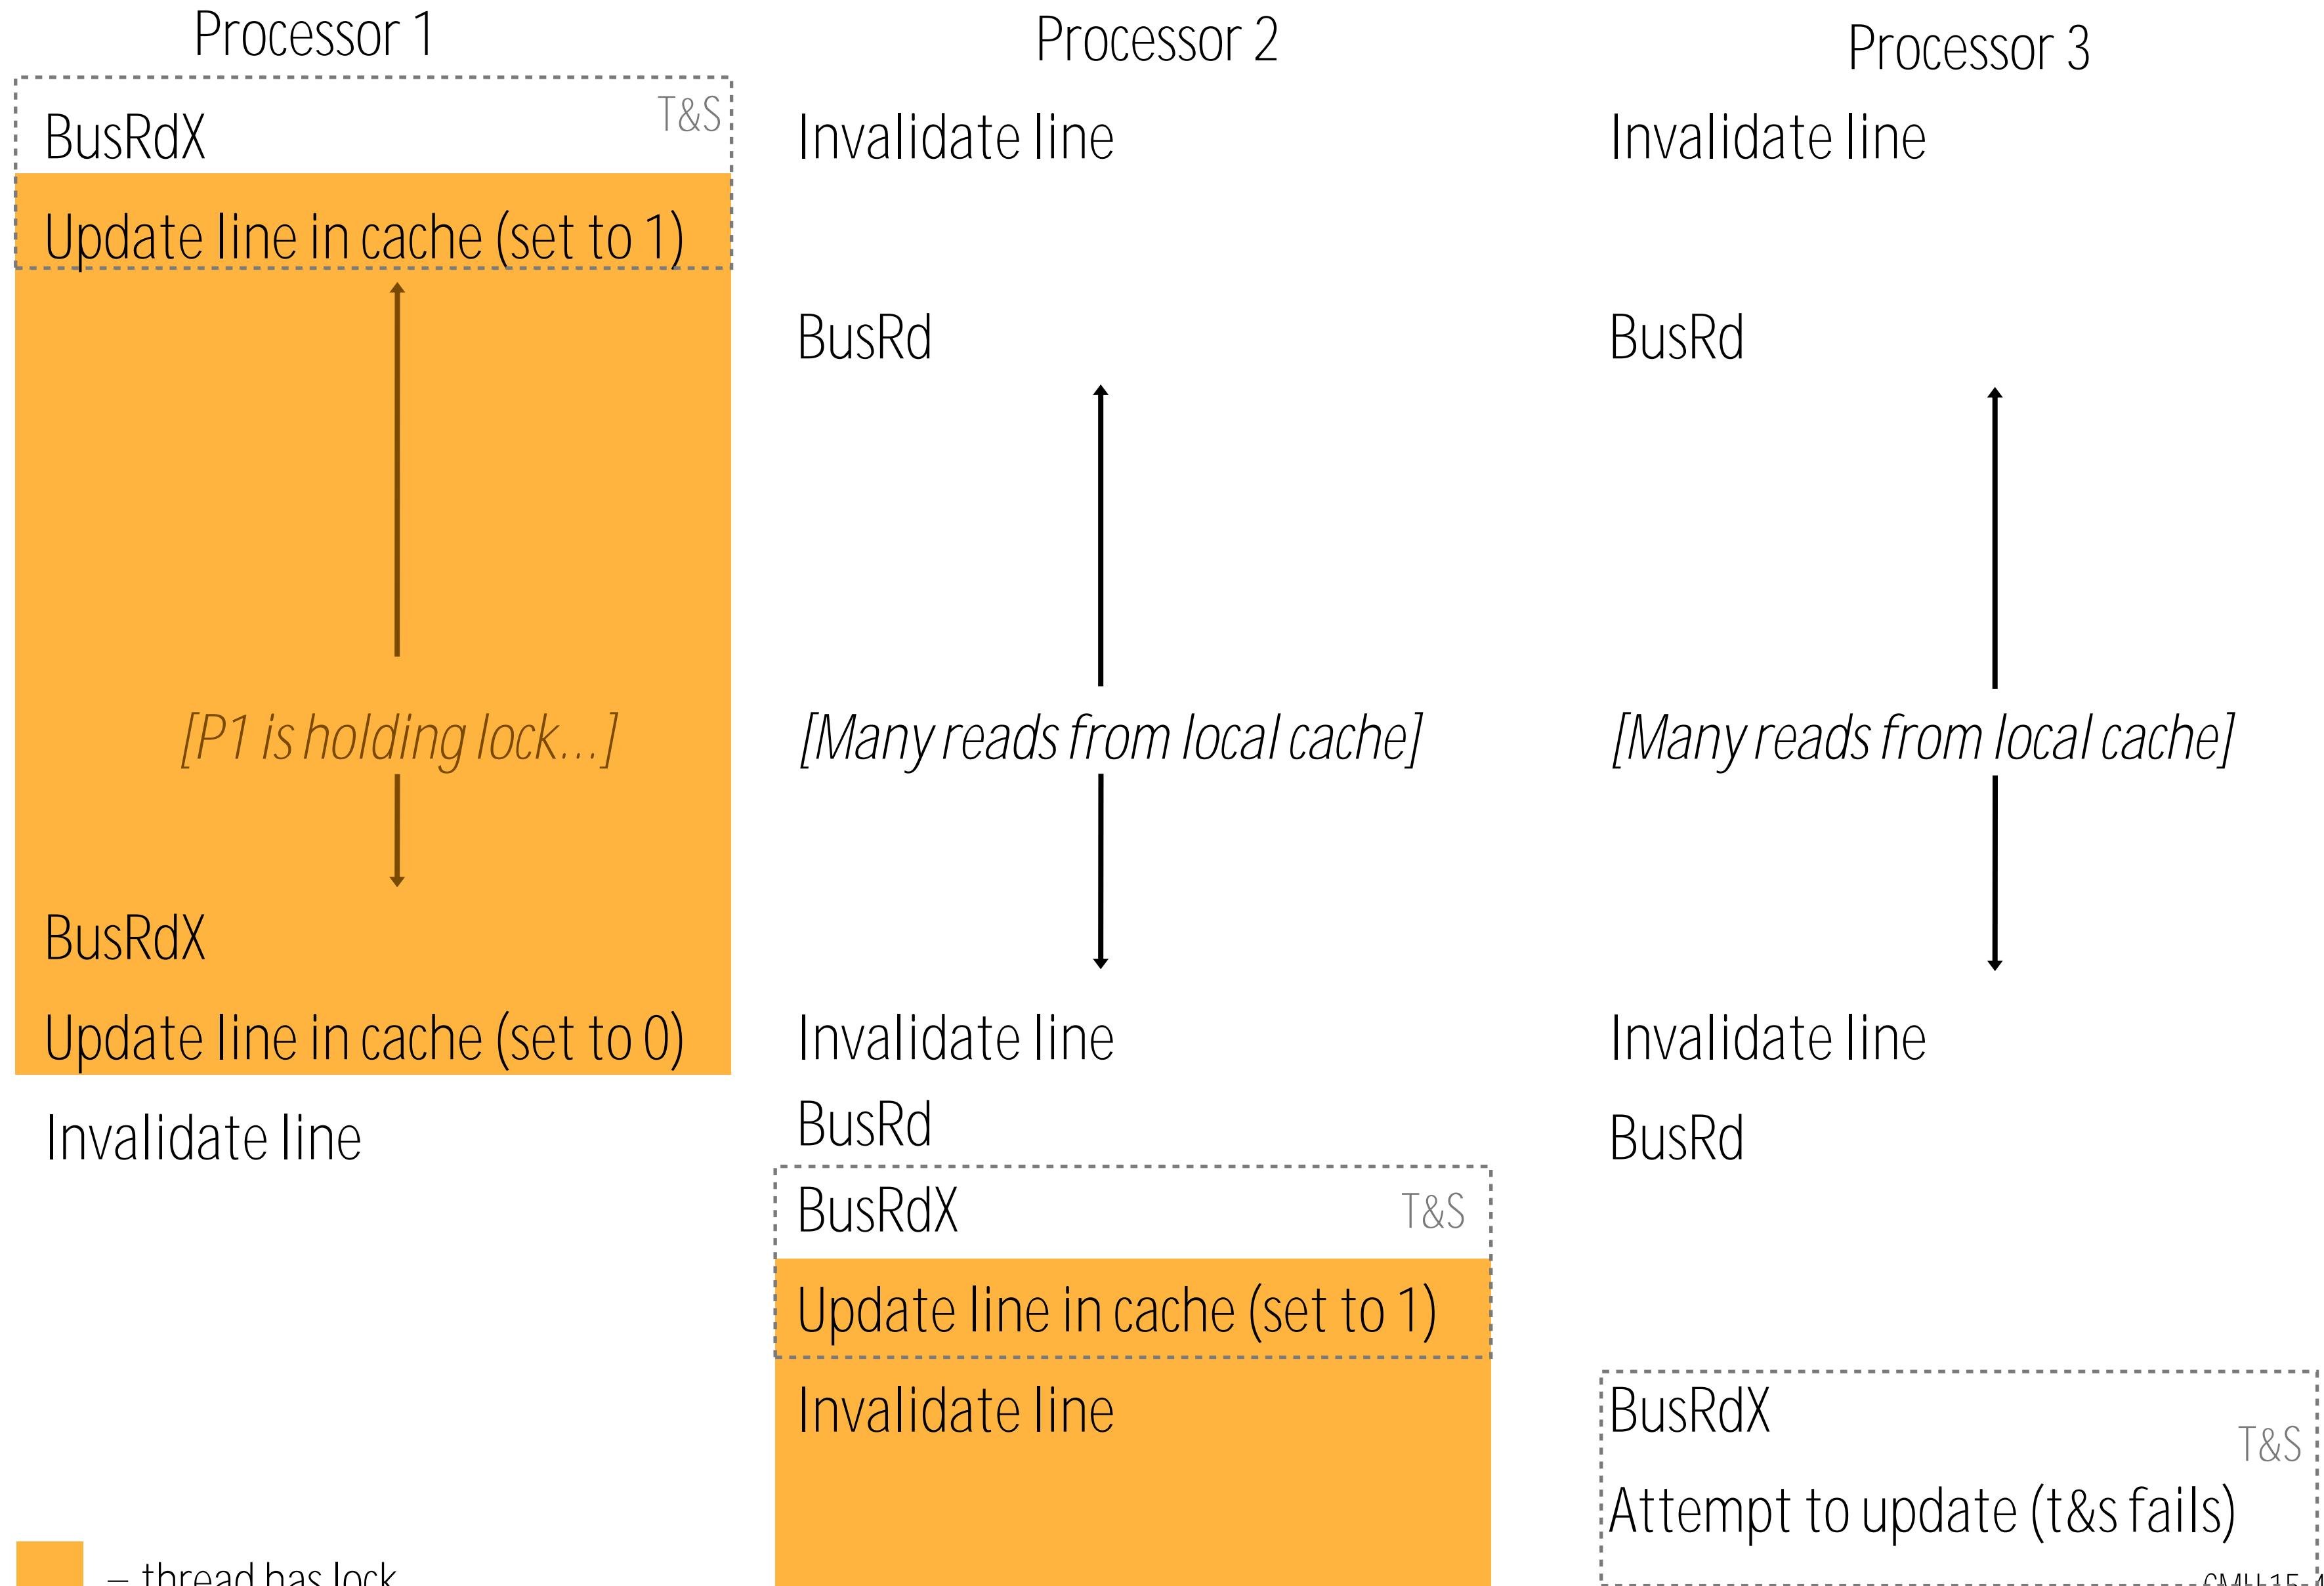

```
void Lock(int* lock) {
    while (1) {

        while (*lock != 0); // while another processor has the lock...

        if (test_and_set(*lock) == 0) // when lock is released, try to acquire it
            return;
    }
}

void Unlock(volatile int* lock) {
    *lock = 0;
}
```

Test-and-test-and-set lock: coherence traffic

Test-and-test-and-set characteristics

- Slightly higher latency than test-and-set in uncontented case
 - Must test... then test-and-set
- Generates much less interconnect traffic
 - One invalidation, per waiting processor, per lock release ($O(P)$ invalidations)
 - This is $O(P^2)$ interconnect traffic if all processors have the lock cached
 - Recall: test-and-set lock generated one invalidation per waiting processor per test
- More scalable (due to less traffic)
- Storage cost unchanged (one int)
- Still no provisions for fairness

Test-and-set lock with back off

Upon failure to acquire lock, delay for awhile before retrying

```
void Lock(volatile int* l) {  
    int amount = 1;  
    while (1) {  
        if (test_and_set(*l) == 0)  
            return;  
        delay(amount);  
        amount *= 2;  
    }  
}
```

- Same uncontended latency as test-and-set, but potentially higher latency under contention. Why?
- Generates less traffic than test-and-set (not continually attempting to acquire lock)
- Improves scalability (due to less traffic)
- Storage cost unchanged (still one int for lock)
- Exponential back-off can cause severe unfairness
 - Newer requesters back off for shorter intervals

Ticket lock

Main problem with test-and-set style locks: upon release, all waiting processors attempt to acquire lock using test-and-set

```
struct lock {
    volatile int next_ticket;
    volatile int now_serving;
};

void Lock(lock* l) {
    int my_ticket = atomic_increment(&l->next_ticket);    // take a “ticket”
    while (my_ticket != l->now_serving);                      // wait for number
}                                                               // to be called

void unlock(lock* l) {
    l->now_serving++;
}
```

No atomic operation needed to acquire the lock (only a read)

Result: only one invalidation per lock release (O(P) interconnect traffic)

Array-based lock

Each processor spins on a different memory address

Utilizes atomic operation to assign address on attempt to acquire

```
struct lock {
    volatile padded_int status[P];      // padded to keep off same cache line
    volatile int head;
};

int my_element;

void Lock(lock* l) {
    my_element = atomic_circ_increment(&l->head);      // assume circular increment
    while (l->status[my_element] == 1);
}

void unlock(lock* l) {
    l->status[my_element] = 1;
    l->status[circ_next(my_element)] = 0;              // next() gives next index
}
```

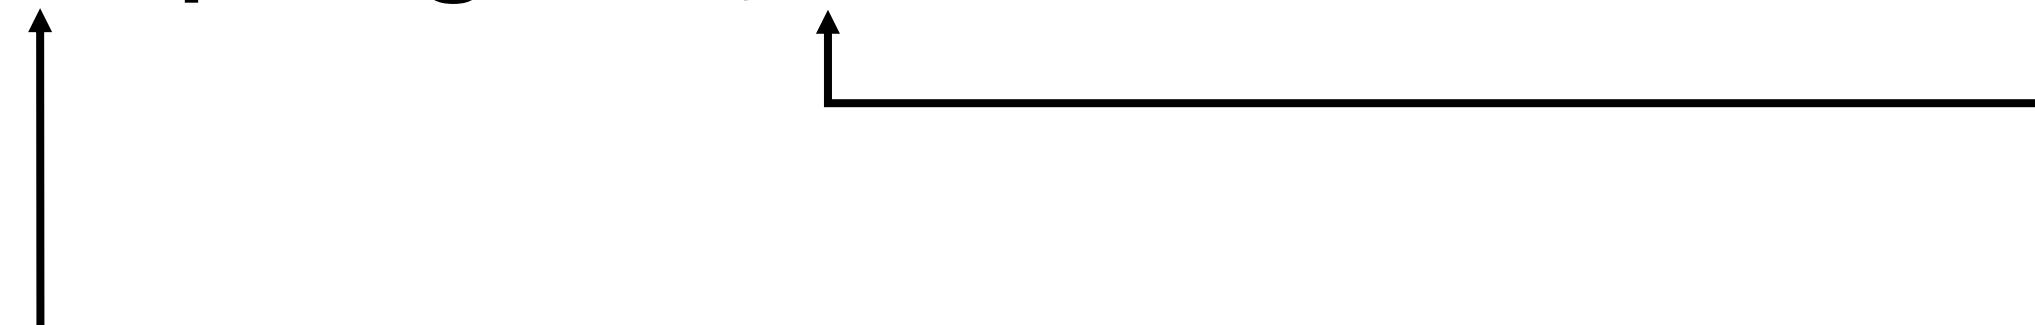

O(1) interconnect traffic per release, but lock requires space linear in P

Also, the atomic circular increment is a more complex operation (higher overhead)

x86 cmpxchg

- Compare and exchange (atomic when used with lock prefix)

lock cmpxchg dst, src

lock prefix (makes operation atomic)

```
if (dst == EAX)
    ZF = 1 ← x86 accumulator register
    dst = src ← flag register
else
    ZF = 0
    EAX = dst
```

Self-check: Can you implement ASM for atomic test-and-set using **cmpxchg**?

Queue-based Lock (MCS lock)

- Create a queue of waiters
 - Each thread allocates a local space on which to wait
- Pseudo-code:
 - glock – global lock
 - mlock – my lock (state, next pointer)

```
AcquireQLock(*glock, *mlock)
{
    mlock->next = NULL;
    mlock->state = UNLOCKED;
    ATOMIC();
    prev = glock
    *glock = mlock
    END_ATOMIC();
    if (prev == NULL) return;
    mlock->state = LOCKED;
    prev->next = mlock;
    while (mlock->state == LOCKED)
        ; // SPIN
}
```

```
ReleaseQLock(*glock, *mlock)
{
    do {
        if (mlock->next == NULL) {
            x = CMPXCHG(glock, mlock, NULL);
            if (x == mlock) return;
        }
        else
        {
            mlock->next->state = UNLOCKED;
            return;
        }
    } while (1);
}
```

Implementing Barriers

Implementing a centralized barrier

(Based on shared counter)

```
struct Barrier_t {  
    LOCK lock;  
    int counter;    // initialize to 0  
    int flag;       // the flag field should probably be padded to  
                    // sit on its own cache line. Why?  
};  
  
// barrier for p processors  
void Barrier(Barrier_t* b, int p) {  
    lock(b->lock);  
    if (b->counter == 0) {  
        b->flag = 0;          // first thread arriving at barrier clears flag  
    }  
    int num_arrived = ++(b->counter);  
    unlock(b->lock);  
  
    if (num_arrived == p) { // last arriver sets flag  
        b->counter = 0;  
        b->flag = 1;  
    }  
    else {  
        while (b->flag == 0); // wait for flag  
    }  
}
```

Does it work? Consider:
do stuff ...
Barrier(b, P);
do more stuff ...
Barrier(b, P);

Correct centralized barrier

```
struct Barrier_t {  
    LOCK lock;  
    int arrive_counter; // initialize to 0 (number of threads that have arrived)  
    int leave_counter; // initialize to P (number of threads that have left barrier)  
    int flag;  
};  
  
// barrier for p processors  
void Barrier(Barrier_t* b, int p) {  
    lock(b->lock);  
    if (b->arrive_counter == 0) { // if first to arrive...  
        if (b->leave_counter == P) { // check to make sure no other threads “still in barrier”  
            b->flag = 0; // first arriving thread clears flag  
        } else {  
            unlock(lock);  
            while (b->leave_counter != P); // wait for all threads to leave before clearing  
            lock(lock);  
            b->flag = 0; // first arriving thread clears flag  
        }  
    }  
    int num_arrived = ++(b->arrive_counter);  
    unlock(b->lock);  
  
    if (num_arrived == p) { // last arriver sets flag  
        b->arrive_counter = 0;  
        b->leave_counter = 1;  
        b->flag = 1;  
    }  
    else {  
        while (b->flag == 0); // wait for flag  
        lock(b->lock);  
        b->leave_counter++;  
        unlock(b->lock);  
    }  
}
```

Main idea: wait for all processes to leave first barrier, before clearing flag for entry into the second

Centralized barrier with sense reversal

```
struct Barrier_t {
    LOCK lock;
    int counter;    // initialize to 0
    int flag;       // initialize to 0
};

int local_sense = 0;    // private per processor. Main idea: processors wait for flag
                        // to be equal to local sense

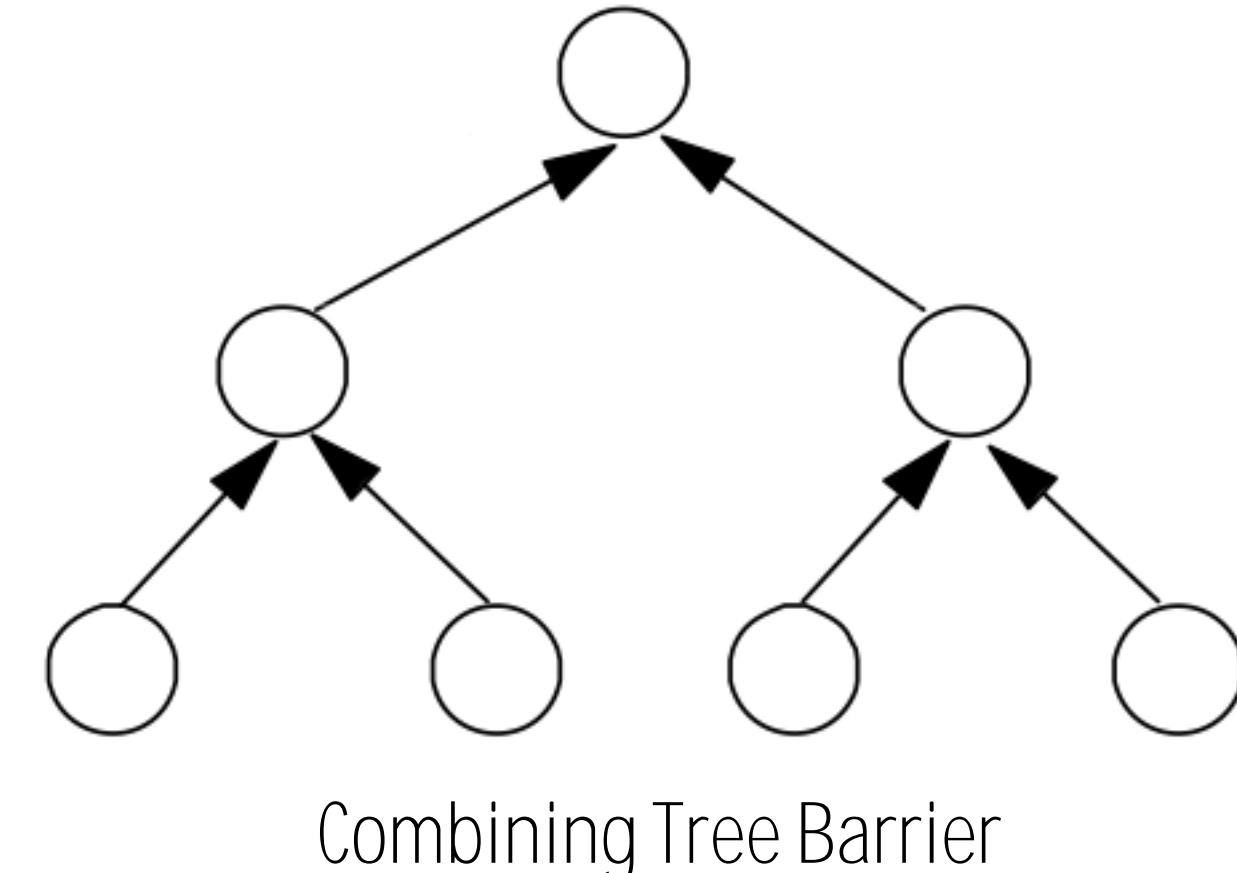

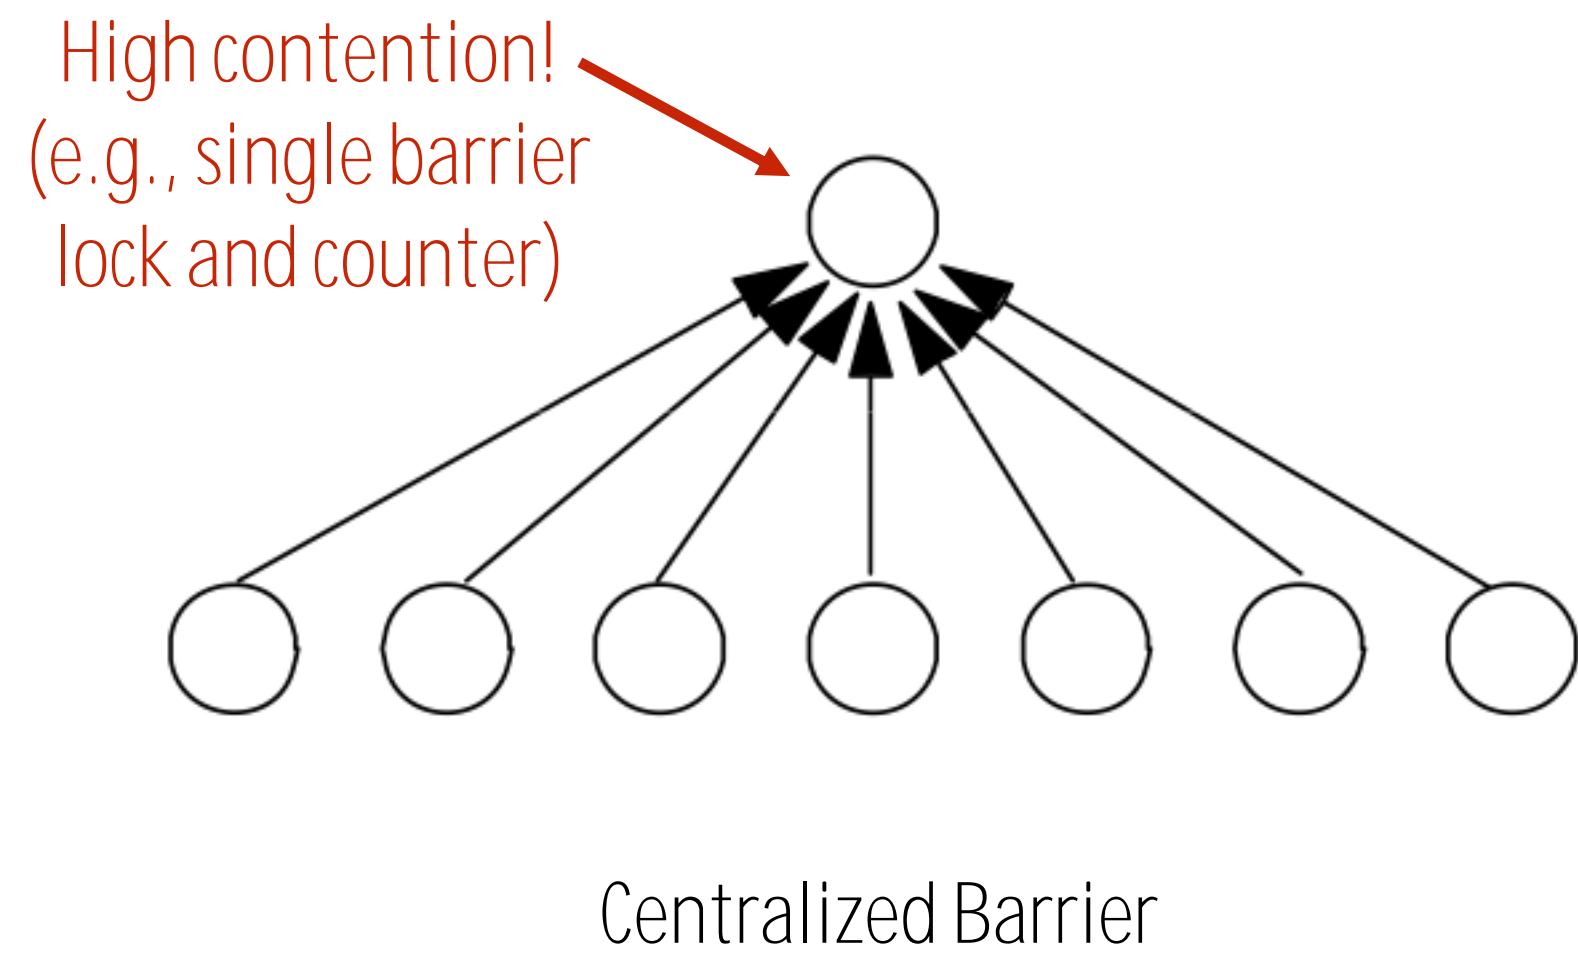

// barrier for p processors
void Barrier(Barrier_t* b, int p) {
    local_sense = (local_sense == 0) ? 1 : 0;
    lock(b->lock);
    int num_arrived = ++(b->counter);
    if (b->counter == p) { // last arriver sets flag
        unlock(b->lock);
        b->counter = 0;
        b->flag = local_sense;
    }
    else {
        unlock(b->lock);
        while (b.flag != local_sense); // wait for flag
    }
}
```

Sense reversal optimization results in one spin instead of two

Centralized barrier: traffic

- $O(P)$ traffic on interconnect per barrier:
 - All threads: 2P write transactions to obtain barrier lock and update counter ($O(P)$ traffic assuming lock acquisition is implemented in $O(1)$ manner)
 - Last thread: 2 write transactions to write to the flag and reset the counter ($O(P)$ traffic since there are many sharers of the flag)
 - $P-1$ transactions to read updated flag
- But there is still serialization on a single shared lock
 - So span (latency) of entire operation is $O(P)$
 - Can we do better?

Combining tree implementation of barrier

- Combining trees make better use of parallelism in interconnect topologies
 - $\lg(P)$ span (latency)
 - Strategy makes less sense on a bus (all traffic still serialized on single shared bus)
- Barrier acquire: when processor arrives at barrier, performs increment of parent counter
 - Process recurses to root
- Barrier release: beginning from root, notify children of release

Coming up...

- Imagine you have a shared variable for which contention is low. So it is unlikely that two processors will enter the critical section at the same time?
- You could hope for the best, and avoid the overhead of taking the lock since it is likely that mechanisms for ensuring mutual exclusion are not needed for correctness
 - **Take a “optimize-for-the-common-case” attitude**
- **What happens if you take this approach and you’re wrong: in the** middle of the critical region, another process enters the same region?
