

Linear Programming III

David Woodruff

Outline

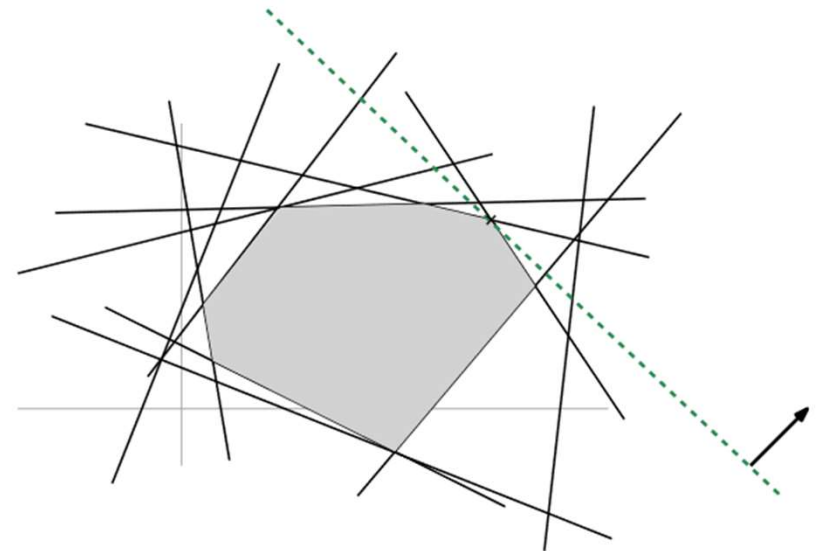

- Another linear programming example – l_1 regression
- Seidel's 2-dimensional linear programming algorithm
- (Time-permitting) Ellipsoid algorithm and simplex algorithm

L1 Regression

- Input: $n \times d$ matrix A with n larger than d , and $n \times 1$ vector b
- Find x with $Ax = b$
- Unlikely an x exists, so instead compute $\min_x \sum_{i=1, \dots, n} |A_i \cdot x - b_i|$
- Solve with linear programming? How to handle the absolute values?
- Create variables s_i for $i = 1, \dots, n$ with $s_i \geq 0$
 - Also have variables x_1, \dots, x_d
- Add constraints $A_i \cdot x - b_i \leq s_i$ and $-(A_i \cdot x - b_i) \leq s_i$ for $i = 1, \dots, n$
- What should the objective function be?
- $\min \sum_{i=1, \dots, n} s_i$

Seidel's 2-Dimensional Algorithm

- Variables x_1, x_2
- Constraints $a_1 \cdot x \leq b_1, \dots, a_m \cdot x \leq b_m$
- Maximize $c \cdot x$
- Start by making sure the program has bounded objective function value

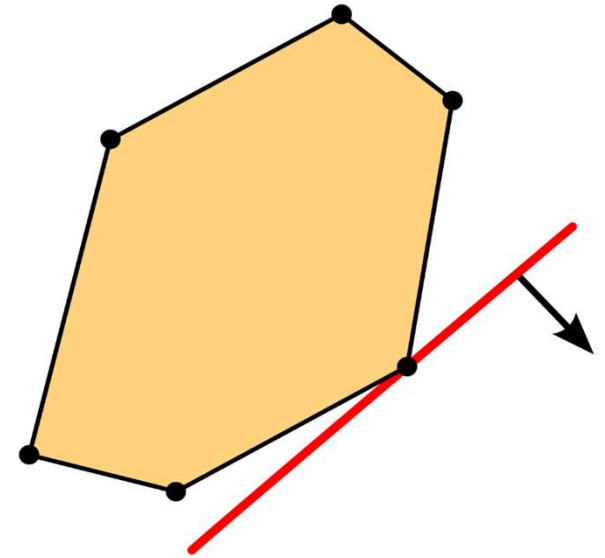

What if the LP is unbounded?

- Add constraints $-M \leq x_1 \leq M$ and $-M \leq x_2 \leq M$ for a large value M
- How large should M be?
- Maximum, if it were bounded, occurs at the intersection of two constraints $ax_1 + bx_2 = c$ and $ex_1 + fx_2 = d$
$$\begin{bmatrix} a & b \\ e & f \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} c \\ d \end{bmatrix}$$
- If a, b, e, f, c, d are specified with L bits, can show $|x_1|, |x_2|$ specified with $O(L)$ bits
- Can evaluate the objective function on each of the 4 corners of the box to find two constraints c_1, c_2 which give the maximum

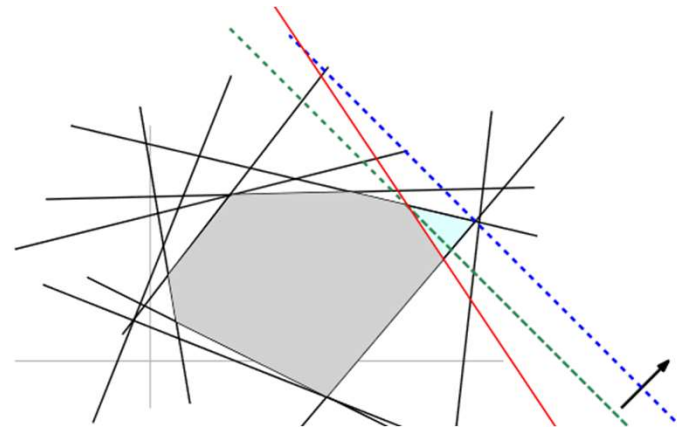

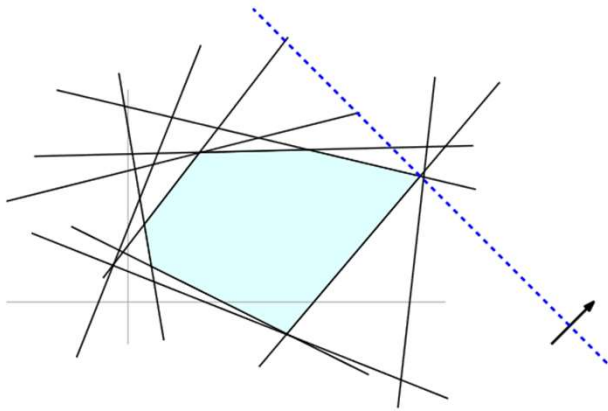

What Convexity Tells Us

- Maximizing a linear function over the feasible region finds a tangent point
- What's a super naïve $O(m^3)$ time algorithm?
- Find the intersection of each pair of constraints, compute its objective function value, and make sure this point is feasible for all constraints
- What's a less naïve $O(m^2)$ time algorithm?

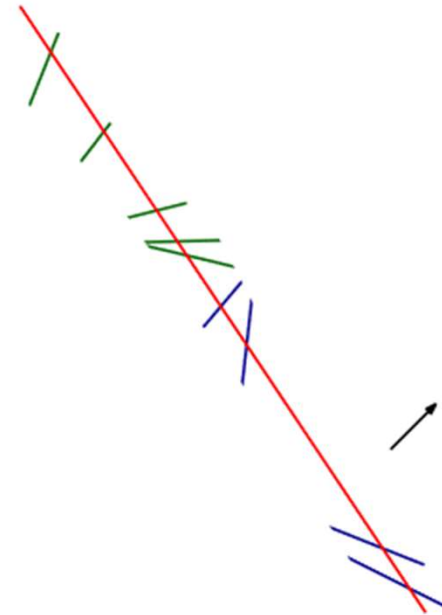

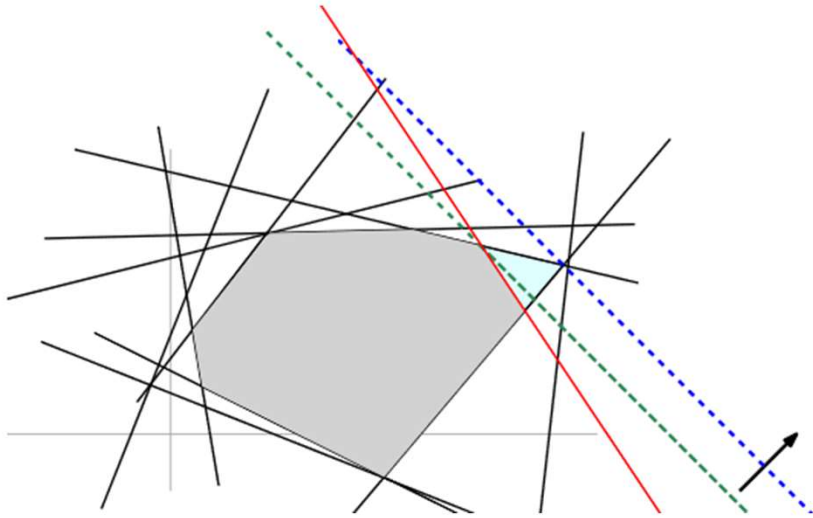

An $O(m^2)$ Time Algorithm

- Order the constraints $c_1, c_2, a_1 \cdot x \leq b_1, \dots, a_m \cdot x \leq b_m$
- Recursively find optimum point x^* of $c_1, c_2, a_1 \cdot x \leq b_2, \dots, a_{m-1} \cdot x \leq b_{m-1}$
- If $a_m x^* \leq b_m$, then x^* is overall optimum
- Otherwise, new optimum intersects the line $a_m x = b_m$
- Need to solve a 1-dimensional problem

1-Dimensional Problem

Takes $O(m)$ time to solve

An $O(m^2)$ Time Algorithm

- Recursively find optimum point x^* of $c_1, c_2, a_1 \cdot x \leq a_1, \dots, a_{m-1} \cdot x \leq b_{m-1}$
- If $a_m x^* \leq b_m$, then x^* is still optimal
- Otherwise, new optimum intersects the line $a_m \cdot x = b_m$
- Solve a 1-dimensional problem in $O(m)$ time
- $T(m) = T(m-1) + O(m) = O(m^2)$ time
- Can we get $O(m)$ time?

Seidel's $O(m)$ Time Algorithm

- Order constraints **randomly**: $c_1, c_2, a_{i_1} \cdot x \leq b_{i_1}, \dots, a_{i_m} \cdot x \leq b_{i_m}$
 - Leave c_1, c_2 at the beginning
- Recursively find the optimum x^* of $c_1, c_2, a_{i_1} \cdot x \leq b_{i_1}, \dots, a_{i_{m-1}} \cdot x \leq b_{i_{m-1}}$
- Case 1: If $a_{i_m} \cdot x^* \leq b_{i_m}$, then x^* is overall optimum
 - $O(1)$ time
- Case 2: If $a_{i_m} \cdot x^* > b_{i_m}$, then we need to intersect the line $a_{i_m} \cdot x = b_{i_m}$ with each other line $a_{i_m} \cdot x = b_m$ and solve a 1-dimensional problem in $O(m)$ time

Seidel's $O(m)$ Time Algorithm

- Let x^* be the optimum point of $c_1, c_2, a_{i_1} \cdot x \leq b_{i_1}, \dots, a_{i_{m-1}} \cdot x \leq b_{i_{m-1}}$
- What is the chance that $a_{i_m} \cdot x^* > b_{i_m}$?
- Suppose the optimum x' of $c_1, c_2, a_{i_1} \cdot x \leq b_{i_1}, \dots, a_{i_m} \cdot x \leq b_{i_m}$ is the intersection of two constraints $a_{i_j} \cdot x = b_{i_j}$ and $a_{i_{j'}} \cdot x = b_{i_{j'}}$
- If we've seen these two constraints, then new constraint $a_{i_m} \cdot x \leq b_{i_m}$ can't change the optimum. Otherwise, overall optimum would change
- Expected time for processing the last constraint is at most
$$(1-2/m) \cdot O(1) + (2/m) \cdot O(m) = O(1)$$

Seidel's $O(m)$ Time Algorithm

- We process the randomly ordered constraints:

$$c_1, c_2, a_{i_1} \cdot x \leq b_{i_1}, \dots, a_{i_m} \cdot x \leq b_{i_m}$$

- When processing the last constraint of:

$$c_1, c_2, a_{i_1} \cdot x \leq b_{i_1}, \dots, a_{i_j} \cdot x \leq b_{i_j}$$

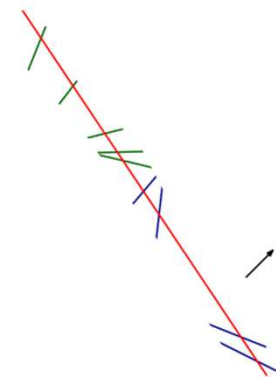

since this prefix of constraints is also in random order, the expected time is

$$(1-2/j) \cdot O(1) + (2/j) \cdot O(j) = O(1)$$

- The expected total time to process m constraints is $\sum_j O(1) = O(m)$
- Formally, let $T(m)$ be the expected time to process all m constraints
$$\begin{aligned} T(m) &\leq (1-2/m) O(1) + (2/m) \cdot O(m) + T(m-1) \\ &= O(1) + T(m-1) \\ &= O(m) \end{aligned}$$

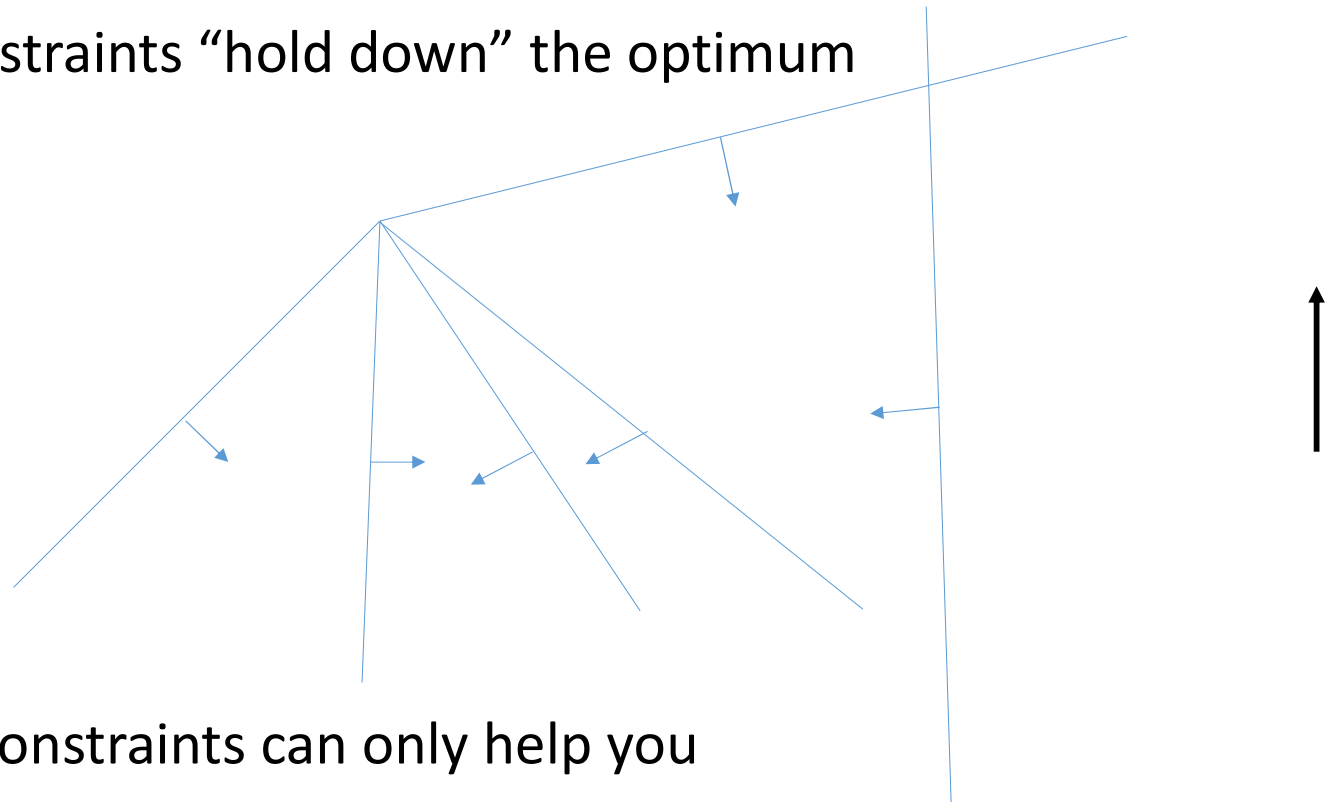

What if the LP is Infeasible?

- Let j be the smallest index for which $c_1, c_2, a_{i_1} \cdot x \leq b_{i_1}, \dots, a_{i_j} \cdot x \leq b_{i_j}$ is infeasible. That is, $c_1, c_2, a_{i_1} \cdot x \leq b_{i_1}, \dots, a_{i_{j-1}} \cdot x \leq b_{i_{j-1}}$ is feasible
- Since $a_{i_1} \cdot x \leq b_{i_1}, \dots, a_{i_{j-1}} \cdot x \leq b_{i_{j-1}}$ is randomly ordered, we spend an expected $O(m)$ time to process such constraints
- When processing $a_{i_j} \cdot x \leq b_{i_j}$ we will find the constraints are infeasible in $O(m)$ time when solving the 1-dimensional problem

What If More than 2 lines Intersect at a Point?

- 2 of the constraints “hold down” the optimum

- Additional constraints can only help you

Higher Dimensions?

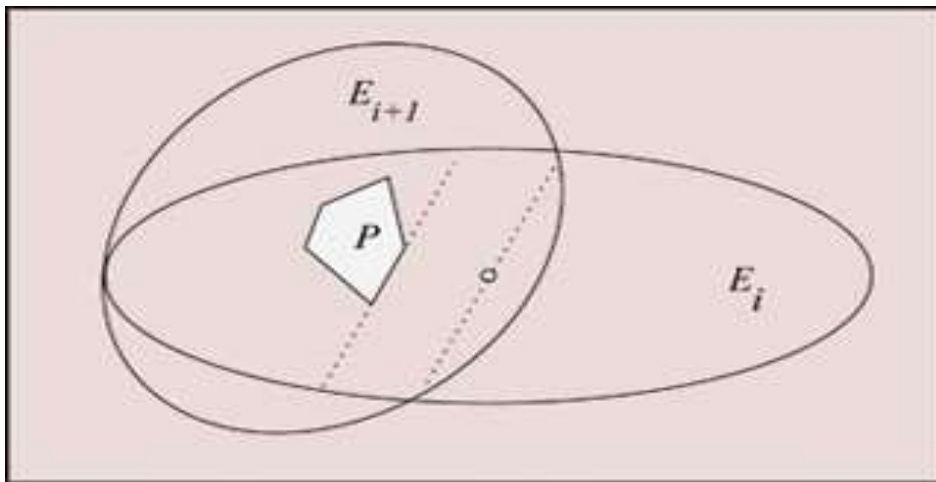

- The probability that our optimum changes is now at most d/m instead of $2/m$
- When we find a violated constraint, we need to find a new optimum
- New optimum inside this hyperplane
 - Project each constraint into this hyperplane
 - Solve a $(d-1)$ -dimensional linear program on $m-1$ constraints to find optimum
 - Time is $O(d!m)$

Ellipsoid Algorithm

Solves feasibility problem

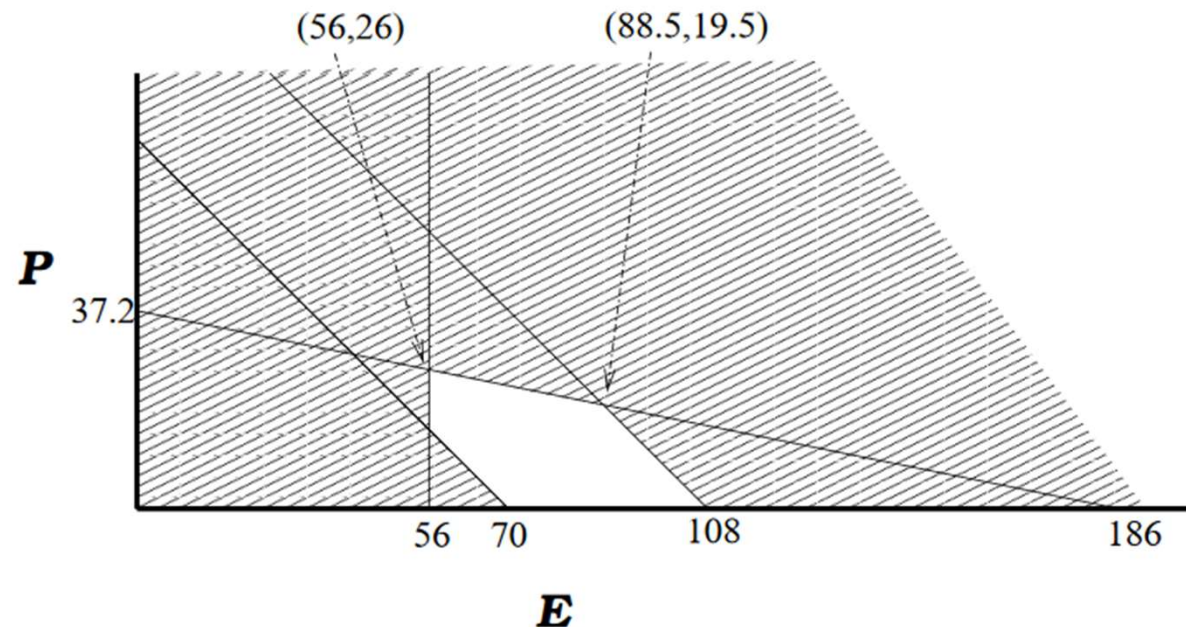

Replace objective function with constraint, do binary search

Replace “maximize $x_1 + x_2$ ” with $x_1 + x_2 \geq \lambda$

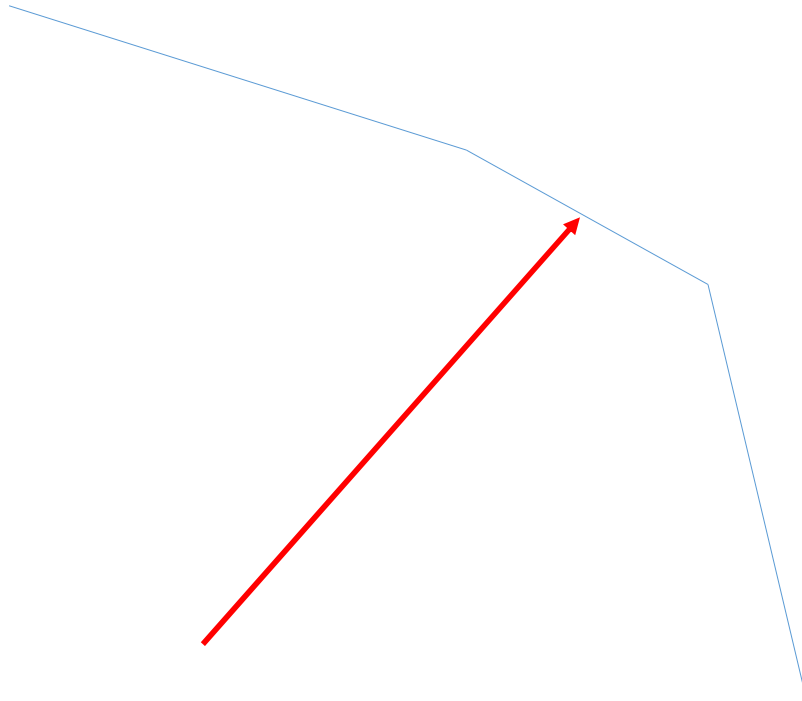

Can handle exponential number of constraints if there's a separation oracle

Simplex Algorithm

- Start at vertex of the feasible region (polyhedron in high dimensions)
- Look at cost of objective function at each neighbor
- Move to neighbor of maximum cost
- Always make progress, but could take exponential time (in high dimensions)

Simplex Algorithm

Get stuck in local maximum?

No, since
feasible set is
convex

Other Annoyances I

- How to start at a vertex of the feasible region?
- $Ax \leq b$
 $x \geq 0$
- What if it's not even feasible?
- Introduce “slack” variable s . Consider:
- $\min s$
subject to $Ax \leq b + s \cdot 1^m$
 $x \geq 0, s \geq 0, s \leq \max_i -b_i$
- Feasible. Can run simplex starting at $x = 0^n$ and $s = \max_i -b_i$
- If original LP is feasible, minimum achieved when $s = 0$, and x that is output is a vertex in the feasible region of original LP

Other Annoyances II

- What if the feasible region is unbounded?
 - Ok, as long as objective function is bounded
- What if objective function is unbounded?
 - Output ∞ , how to detect this?
- Many ways
 - use duality
 - see if you hit a constraint $-M \leq x_i \leq M$ for some i and a very large value M
