Computer Networking

Lecture 8 – DNS

Peter Steenkiste

Justine Sherry

Fall 2017

www.cs.cmu.edu/~prs/15-441-F17

How Do We Identify Hosts?

- Hosts have a

- host name

www.google.com

- IP address

- MAC address

DNS

ARP

Application

Presentation

Session

Transport

Network

Data link

Physical

Host Names & Addresses

- Host addresses: *e.g., 169.229.131.109*
 - a number used by protocols
 - conforms to network structure (the “where”)
- Host names: *e.g., linux.andrew.cmu.edu*
 - mnemonic name usable by humans
 - conforms to organizational structure (the “who”)
- The Domain Name System (DNS) is how we map from one to the other
 - a **directory service** for hosts on the Internet

Why bother?

- Convenience
 - Easier to remember www.google.com than 74.125.239.49
- Provides a level of indirection!
 - Decoupled names from addresses
 - Many uses beyond just naming a specific host

DNS provides Indirection

- Addresses can **change** underneath
 - Move `www.cnn.com` to a new IP address
 - Humans/apps are unaffected
- Name could map to **multiple** IP addresses
 - Enables load-balancing
- **Multiple names** for the same address
 - E.g., many services (mail, www, ftp) on same machine
- Allowing “host” names to evolve into “service” names

DNS: Early days

- Mappings stored in a hosts.txt file (in /etc/hosts)
 - maintained by the Stanford Research Institute (SRI)
 - new versions periodically copied from SRI (via FTP)
- As the Internet grew this system broke down
 - SRI couldn't handle the load
 - conflicts in selecting names
 - hosts had inaccurate copies of hosts.txt
- The Domain Name System (DNS) was invented to fix this

Obvious Solutions (1)

Why not centralize DNS?

- Distant centralized database
 - Traffic volume
- Single point of failure
- Single point of update
- Single point of control
- Doesn't *scale*!

Goals?

- Scalable
 - many names
 - many updates
 - many users creating names
 - many users looking up names
- Highly available
- Correct
 - no naming conflicts (uniqueness)
 - consistency
- Lookups are fast

How?

- Partition the namespace
- Distribute administration of each partition
 - Autonomy to update my own (machines') names
 - Don't have to track everybody's updates
- Distribute name resolution for each partition
- *How should we partition things?*

Key idea: hierarchical distribution

Three intertwined hierarchies

- Hierarchical namespace
 - As opposed to original flat namespace
- Hierarchically administered
 - As opposed to centralized administrator
- Hierarchy of servers
 - As opposed to centralized storage

DNS Design: Hierarchy Definitions

- Each node in hierarchy stores a list of names that end with same suffix
 - Suffix = path up tree
- E.g., given this tree, where would following be stored:
 - Fred.com
 - Fred.edu
 - Fred.cmu.edu
 - Fred.cmcl.cs.cmu.edu
 - Fred.cs.mit.edu

DNS Design: Zone Definitions

- Zone = contiguous section of name space
 - E.g., Complete tree, single node or subtree
- A zone has an associated set of name servers
 - Must store list of names and tree links

Subtree

Single node

Complete Tree

Server Hierarchy

- Top of hierarchy: Root servers
 - Location hardwired into other servers
- Next Level: Top-level domains
 - .com, .edu, .uk, etc.
 - Managed professionally

New TLDs starting in 2012
... expect to see more
in the future.
- Bottom Level: **Authoritative** DNS servers
 - Actually store the name-to-address mapping
 - Maintained by the corresponding administrative authority

Server Hierarchy

- Every server knows the address of the root name server
 - Root servers know the address of all TLD servers
 - ...
 - An authoritative DNS server stores name-to-address mappings (“resource records”) for all DNS names in the domain that it has authority for
- Each server stores a subset of the total DNS database
- Each server can discover the server(s) responsible for any portion of the hierarchy

DNS Root

- Located in Virginia, USA

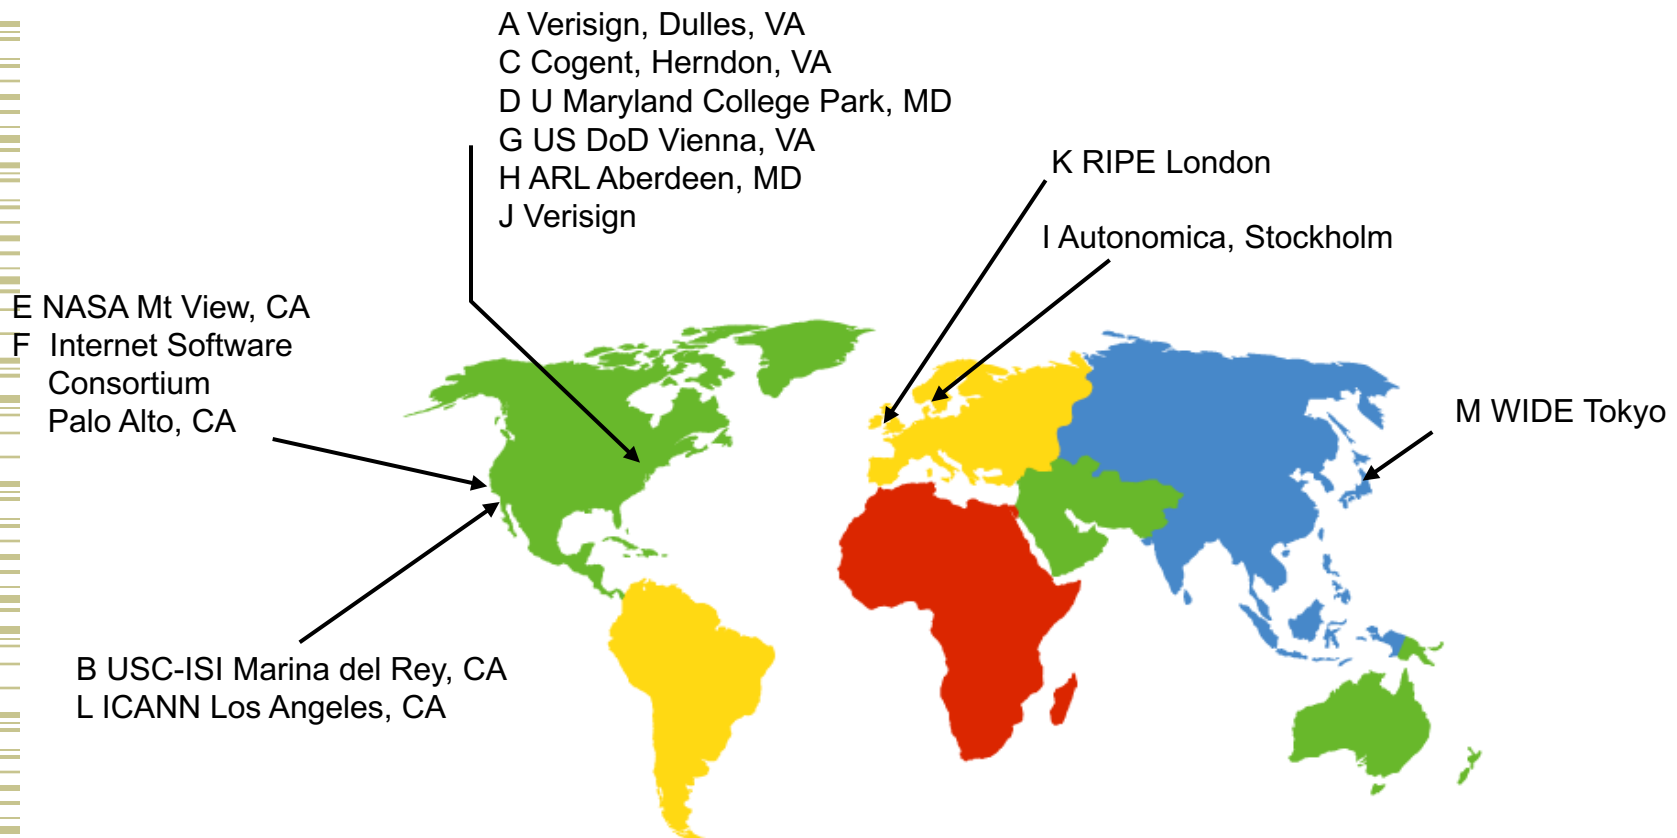

Verisign, Dulles, VA

DNS Root Servers

- 13 root servers (labeled A-M; see <http://www.root-servers.org/>)

DNS Root Servers

- 13 root servers (labeled A-M; see <http://www.root-servers.org/>)
- Replicated via **any-casting**

Anycast in a nutshell

- Routing finds shortest paths to destination
- What happens if multiple machines advertise the same address?
- The network will deliver the packet to the closest machine with that address
- This is called “anycast”
 - Very robust
 - Requires no modification to routing algorithms

Programmer's View of DNS

- Conceptually, programmers can view the DNS database as a collection of millions of *host entry structures*:

```
/* DNS host entry structure */  
struct addrinfo {  
    int    ai_family;           /* host address type (AF_INET) */  
    size_t ai_addrlen;         /* length of an address, in bytes */  
    struct sockaddr *ai_addr;   /* address! */  
    char  *ai_canonname;        /* official domain name of host */  
    struct addrinfo *ai_next;   /* other entries for host */  
};
```

- Functions for retrieving host entries from DNS:
 - `getaddrinfo`: query key is a DNS host name.
 - `getnameinfo`: query key is an IP address.

Properties of DNS Host Entries

- Different kinds of mappings are possible:
 - Simple case: 1-1 mapping between domain name and IP addr:
 - `kittyhawk.cmcl.cs.cmu.edu` maps to `128.2.194.242`
 - Multiple domain names maps to the same IP address:
 - `eeecs.mit.edu` and `cs.mit.edu` both map to `18.62.1.6`
 - Single domain name maps to multiple IP addresses:
 - `www.google.com` maps to multiple IP addrs.
 - Some valid domain names don't map to any IP address:
 - for example: `cmcl.cs.cmu.edu`

DNS Records

RR format: (class, name, value, type, ttl)

- DB contains tuples called resource records (RRs)
 - Classes = Internet (IN), Chaosnet (CH), etc.
 - Each class defines value associated with type

FOR IN class:

- | | |
|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <ul style="list-style-type: none">• Type=A<ul style="list-style-type: none">• name is hostname• value is IP address• Type=NS<ul style="list-style-type: none">• name is domain (e.g. foo.com)• value is name of authoritative name server for this domain | <ul style="list-style-type: none">• Type=CNAME<ul style="list-style-type: none">• name is an alias name for some “canonical” (the real) name• value is canonical name• Type=MX<ul style="list-style-type: none">• value is hostname of mailserver associated with name |
|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

Inserting RRs into DNS

- Example: you just created company “FooBar”
- You get a block of IP addresses from your ISP
 - say 212.44.9.128/25
- Register [foobar.com](#) at registrar (e.g., NameCheap)
 - Provide registrar with names and IP addresses of your authoritative name server(s)
 - Registrar inserts RR pairs into the **.com TLD** server:
 - ([foobar.com](#), [dns1.foobar.com](#), NS)
 - ([dns1.foobar.com](#), [212.44.9.129](#), A)
- Store resource records in your server [dns1.foobar.com](#)
 - e.g., type A record for [www.foobar.com](#)
 - e.g., type MX record for [foobar.com](#)

Using DNS (Client/App View)

- Two components
 - Local DNS servers
 - Resolver software on hosts
- Local DNS server (“default name server”)
 - Clients configured with the default server’s address or learn it via a host configuration protocol
- Client application
 - Obtain DNS name (e.g., from URL)
 - Triggers DNS request to its local DNS server

Servers/Resolvers

- Each host has a resolver
 - Typically a library that applications can link to
 - Local name servers hand-configured (e.g. `/etc/resolv.conf`)
- Name servers
 - Either responsible for some zone or...
 - Local servers
 - Do lookup of distant host names for local hosts
 - Typically answer queries about local zone

recursive DNS query

Goals – how are we doing?

- Scalable
 - many names
 - many updates
 - many users creating names
 - many users looking up names
- Highly available

Per-domain availability

- DNS servers are **replicated**
 - Primary and secondary name servers required
 - Name service available if at least one replica is up
 - Queries can be load-balanced between replicas
- Try alternate servers on timeout
 - **Exponential backoff** when retrying same server

Caching

- Caching of DNS responses at all levels
- Reduces load at all levels
- Reduces delay experienced by DNS client

DNS Caching

- How DNS caching works
 - DNS servers cache responses to queries
 - Responses include a “time to live” (TTL) field
 - Server deletes cached entry after TTL expires
- Why caching is effective
 - The top-level servers very rarely change
 - Popular sites visited often → local DNS server often has the information cached

Negative Caching

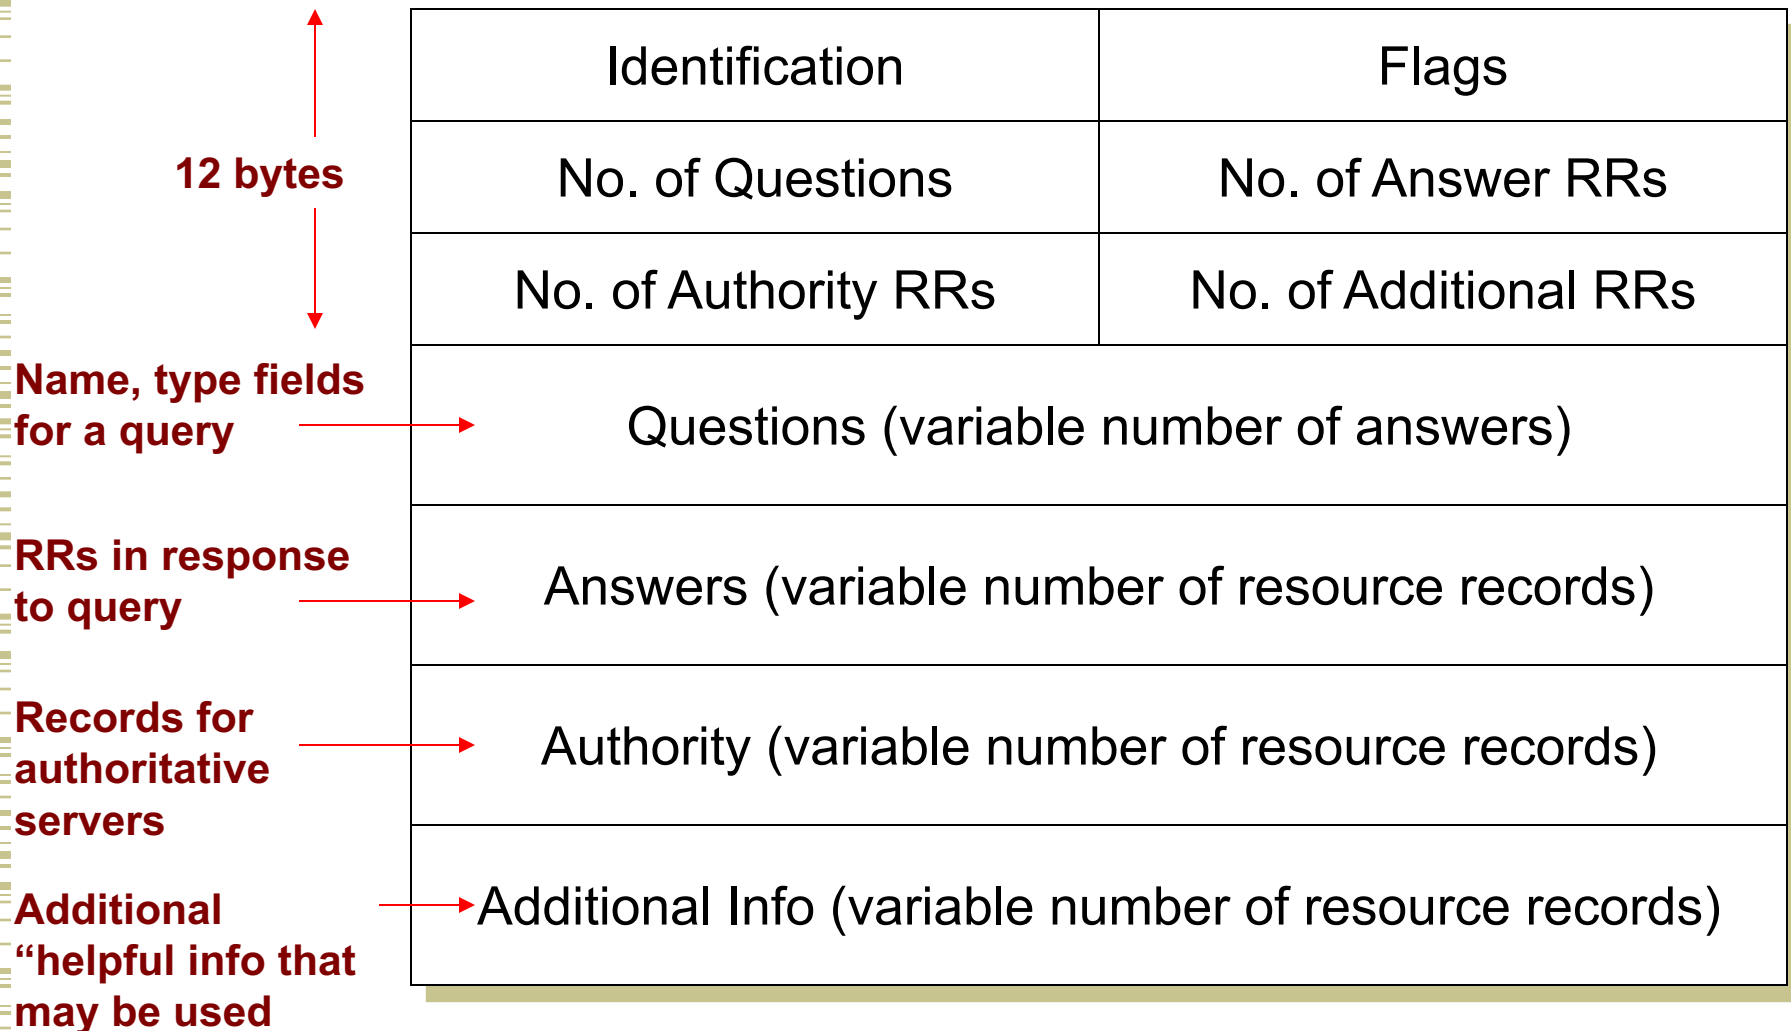

- Remember things that don't work
 - Misspellings like *www.cnn.comm* and *www.cnnn.com*
 - These can take a long time to fail the first time
 - Good to remember that they don't work
 - ... so the failure takes less time the next time around
- Negative caching is optional

Goals – how are we doing?

- Scalable
 - many names
 - many updates
 - many users creating names
 - many users looking up names
- Highly available
- Correct
 - no naming conflicts (uniqueness)
 - consistency
- Lookups are fast

DNS Message Format

DEMO TIME

- Literally they tell people never do a live demo.
- They never work
- I hope I have Internet connectivity for this.

DNS Header Fields

- Identification
 - Used to match up request/response
- Flags
 - 1-bit to mark query or response
 - 1-bit to mark authoritative or not
 - 1-bit to request recursive resolution
 - 1-bit to indicate support for recursive resolution

How can one attack DNS?

How can one attack DNS?

- Impersonate the local DNS server
 - *give the wrong IP address to the DNS client*
- Denial-of-service the root or TLD servers
 - *make them unavailable to the rest of the world*
- Poison the cache of a DNS server
 - *trick the server into caching the wrong IP address*

Enter: DNSSEC

An extension to DNS to improve DNS security.

What does DNSSEC provide

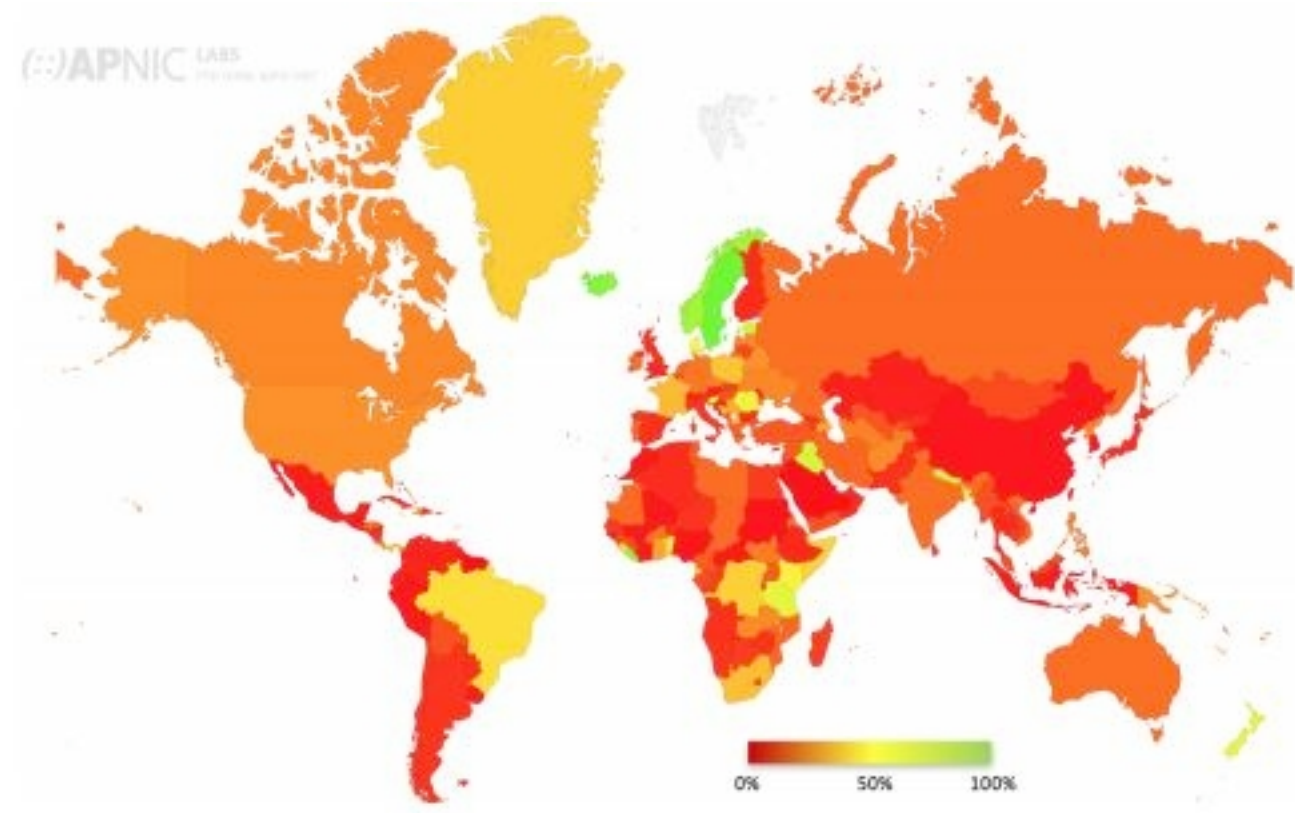

- provides message authentication and integrity verification through cryptographic signatures
 - You know who provided the signature
 - No modifications between signing and validation
- It does not provide authorization
- It does not provide confidentiality
- It does not provide protection against DDOS

DNSSEC: Deployment Status

- 89% of top-level domains (TLDs) zones signed.
 - ~47% of country-code TLDs (ccTLDs) signed.
- Second-level domains (SLDs) vary widely:
 - Over 2.5 million .nl domains signed (~45%) (Netherlands). [\[1\]](#)
 - ~88% of measured zones in .gov are signed.
 - Over 50% of .cz (Czech Republic) domains signed.
 - ~24% of .br domains signed (Brazil). [\[2\]](#)
 - While only about 0.5% of zones in .com are signed, that percentage represents ~600,000 zones.

DNSSEC: Deployment Status

Important Properties of DNS

- Easy unique, human-readable naming
- Hierarchy helps with scalability
- Caching lends scalability, performance
- Not strongly consistent
- Trust model has some problems!

Next Lecture

- How do forwarding tables get built?
- Routing protocols
 - Distance vector routing
 - Link state routing
